In the action of walking the centre of gravity is alternately moved by one part of the extremities and sustained by the other, so that the body is never at one time completely suspended above the ground. In walking on two legs the animal first advances one foot, so that the advanced leg makes an obtuse angle with the tarsus, while that behind makes an acute angle. From the resistance of the ground to the foot behind, it is necessary to raise the heel and leg; and to do this, the trunk, supported on the *pelvis*, is moved upwards, forwards, and a little to one side, moving round the fixed foot as a centre. Thus the other leg is thrown forward, and rests its foot upon the ground, while the other now forms an acute angle with its leg, and gives occasion to a similar motion of the trunk on the other side. In these motions the extensor muscles act first, and the flexors immediately after. As the undulatory motion that necessarily attends walking cannot be perfectly regulated on both sides, it is evident that a person cannot walk on a perfectly straight line, and that to walk in a direct course requires the assistance of the eyes. Hence we find, that in the experiments which are sometimes made to walk or drive a wheel-barrow directly to a certain object blindfold, the attempt is uniformly unsuccessful.

In walking upon four feet, the quadruped first slightly bends the hind legs and then extends them so as to throw the body forward; and now, as by this motion the fore legs incline backward, the animal would fall if he did not throw forward the fore legs to support him. When this is done the body is drawn up on the fore legs, and the former motions repeated. In this motion, however, the two fore legs, or the two hind are never used at once; but the step is performed by one leg belonging to the hind and one to the fore pair, though these are not always of the same side. Those animals which have their fore-legs considerably shorter than their hind, as jerboas, kangaroos, hares, rabbits, and frogs, rather leap than walk.

In *leaping*, the body is for a time raised completely from the earth. This action is performed by first throwing the sacral articulations into an unusual degree of flexion, and then suddenly and strongly exerting all their extensor muscles. The force and extent of the leap depend on the proportional length of the bones and strength of the muscles. Hence those animals that have the sacral extremities considerably longer and thicker than the atlantal, leap the best. The smaller the animal, too, the greater proportionally is the leap; and perhaps there is no animal that exceeds the flea in the length and agility of leaping, it being computed, at a moderate leap, to measure 200 times its own length.

Several animals that have no feet perform a motion analogous to leaping; that is, they spring from the surface on which they are moving into the air. Serpents do this by folding up their bodies in a spiral form, and then suddenly uncoiling them. Salmon, and some other fishes, leap up cataracts, by bending their bodies as much as possible, and then unbending them by a strong elastic spring. Shrimps, and other cray fish, leap by suddenly extending the tail after it has been bent beneath the body; and maggots spring to a distance, by arching their bodies nearly into a circle, and suddenly relaxing them into a straight line.

Running differs from leaping, inasmuch as it is performed by the alternate progression of each leg, while it differs from walking in the body being projected forward at each step, and the hind foot being raised before the other touches the ground. It consists in a series of low bounds, in which the body is inclined forward, in order to place the centre of gravity in a position proper for receiving an impulse from the hinder leg, while the fore leg is moved rapidly forward to prevent falling. The trotting and galloping of quadrupeds are running upon four feet, and they differ from each other in the mode of raising the feet. In trotting, the diagonally opposite feet rise at once and fall at once, each diagonal pair alternately, but so that for a moment all the feet are off the ground. In galloping, the animal raises the fore feet at each step, and throws forward the body by the extension of the hind feet. When the two fore feet touch the ground a little after each other, it is called a canter; when both fore feet touch the ground at once, and are followed by the two hind feet also touching the ground at once, it is a full gallop.

Climbing consists in hanging from and strongly grasping any object capable of being seized by the fingers, toes, or tail, and by successive efforts raising the body in opposition to its weight. Hence those animals are the best climbers that have their paws and feet most deeply cleft, their divisions most flexible, or their claws longest and sharpest. Man is but an indifferent climber, as he can make no use of his feet in this action, and can only grasp the object with his legs, while he holds by his hands. Among quadrupeds, apes and lemurs climb the best, from the form of all their fore feet being similar to that of the human hand. Cats also climb well from the sharpness of their claws. Of birds, woodpeckers, nut-hatches, and those called creepers, also climb by means of their sharp talons. Lizards, chameleons, and some other reptiles, climb well, partly from the length and flexibility of their toes, and partly, in some of them, from the prehensile property of the tail.

Flying, properly so called, is performed only by birds and insects. It may be considered as a succession of leaps, assisted and prolonged by the resistance given to the air by the wings and tail. In commencing its flight, a bird leaps either from the ground or from some elevated object, and unfolds its wings in a horizontal direction. It then suddenly depresses the wings, so as to form an angle with the vertical plane of the body, and the resistance afforded by the air to this motion produces a re-action on the body of the bird, and impels it forward. These actions are repeated; and as long as the wings thus act the bird ascends; and when it wishes to descend, it has only to intermit the action of the wings, and either fall by its own gravity or descend gradually by occasional lesser vibrations. In flying horizontally, a bird does not move long in a straight direction, but describes a succession of curves, alternately ascending and descending in an oblique course. The action of the tail in flying is various. When it is depressed, it impels the bird upwards, and *vice versa*; and when moved to one side or to the other, it assists in turning the bird's body in an opposite direction.

Butterflies, and other winged insects, are, from the lightness of their bodies, easily supported in the atmosphere by means of the gentle and continued vibrations of their wings.

Several animals besides these imitate the motion of flying. Bats, flying lemurs, flying squirrels, and flying dragons, have a membranous expansion extended between the phalanxes of the fore toes, and sometimes from these to the thighs, by means of which, when they leap from one tree, they are easily supported in their gradual progress towards another. The motion of the flying-fish, by which it raises itself from the water and remains for a short period in the air, as some suppose, more nearly resembles flying than that of the last-mentioned animals; but it is worthy of inquiry, whether the motion of the flying-fish out of the water ought to be considered any thing else than a long leap, which the great length of its pectoral fins enables it to take.

Swimming is performed by a great variety of animals besides fishes. It is probable that almost all quadrupeds are capable of this motion; and we know that the bulkiest among them, the elephant and hippopotamus, swim with great facility. Many of them, as seals and walrusses, are even considered as amphibious; and the polar bear passes much of its time in the water. Among the birds, all those that are web-footed naturally swim; and there are few reptiles to whom this motion is not familiar. The action is of course differently performed, according to the shape and habits of the animal. Quadrupeds and birds swim by employing their feet as oars or paddles, and probably their tail as a rudder. Cetaceous animals, seals and walrusses, impel their bodies through the water by paddling with their atlantal extremities or paws, and moving their sacral extremities or tail in various directions, according to the required velocity and line of their course. Of reptiles, frogs swim in a manner similar to man, by throwing their fore legs forward and their hind backward at the same time.

Fishes, however, are the only animals that swim with perfect ease, as the form of their bodies, the number of their fins, and the air or swimming bladder, with which most of them are provided, all contribute towards this purpose. They are impelled through the water chiefly by the pectoral and ventral fins, and by the broad vertical fin that terminates the tail, while the swimming bladder, as it is more or less compressed by its appropriate muscles, increases or diminishes their specific gravity, and thus enables them to descend or ascend at pleasure. The air bladder is so important an organ in the economy of fishes, that we find those in whom it is wanting, as the flat fish, always remain near the bottom, though their fins enable them to make way through the water horizontally.

Chap. II. Of Sensation.

The organs of sensation are either general or particular. The former, commonly called the *nervous system*, comprehends the *encephalon*, the *spinal marrow*, and the *nerves*; the latter constitute the organs of the senses.

Sect. I. *Of the Nervous System.*

All the brainy mass contained within the cavity of the skull is hence called *encephalon*. It consists of various parts; and a perpendicular section longitudinally through its middle divides it into two equal and similar halves. On cutting through the frontal, temporal, parietal, and occipital bones, by a horizontal section just above the eyes and ears, and removing these bones, we first observe a dense and thick vascular membrane, called by anatomists *dura mater*, which adheres to the bones in various parts, but more especially to the upper longitudinal line, extending from the nose to the occiput. On cutting through this membrane, after the manner of the former section, we find that its middle longitudinal upper part is prolonged downwards, forming a partition between the two halves, or, as they are called, hemispheres of the brain. This mass, now brought into view, displays, through a thin membrane that lies over it, numerous undulating prominences which are enveloped in a very fine transparent membrane, and are of a reddish grey colour. These are the convolutions of the brain. On extending our examination downwards, we find that the two hemispheres are flattened, and pretty smooth, where they were divided by the *dura mater*, and that they are joined near the middle by a central part more solid than the rest. This is called the *callous body*.

On cutting into the substance of the brainy mass, we perceive that it is composed of two very different substances, one external, of a reddish grey colour, called the *cortical* or *cineritious matter*, the other forming the internal or central part of the mass, white and pulpy, though, on a close and careful examination, it is found to be composed of very delicate fibres. This latter has been called the *medullary* substance.

On raising the back parts of the two hemispheres, we find them supported by an expansion which forms a horizontal partition between what is usually called the brain, and a lesser portion of the encephalon, called *cerebellum*, or little brain. This is also composed of two parts, or lobes, united by a middle central portion, and this latter joins the central portion that unites the hemispheres of the brain. On removing the whole brainy mass from the skull, by cutting it across at the bottom of the great occipital hole, and dividing a number of white cords, by which it is connected to the base of the skull, we find that its lower side, which rested on the base, is extremely irregular. In the first place, we see a conical or pyramidal part, which filled up the occipital hole, and which, by some writers, is considered the commencement, by others the termination of the encephalon, and which has been called the *oblong medulla*. Behind this lies the cerebrum, to the fore-part of which the pyramidal portion is united by transverse parts, called *crura*, or legs, and before is seen a transverse broad portion, called *annular tuberosity* or *bridge of Varolius*. Farther on lies a spherical body, called *pituitary gland*. We also see that the lower surface of the cerebellum is marked with circular prominent lines, while the lower surface of the proper brain has convolutions similar to those above. This latter is also seen divided into three unequal parts on each side, the *anterior lobes* lying on the frontal bone, the *middle lobes* lying over the temporal and sphenoidal bones, and the *posterior lobes* lying partly on the occipital bone, and partly on the membrane that separates them from the cerebellum. On cutting vertically into the substance of the cerebellum, we observe an appearance resembling a shrub, that is, a middle white trunk, from which numerous branches pass off on each side; this has been called *arbor vitæ*, or the tree of life.

When we examine more minutely the internal structure of the brain, we find that its substance is in several parts separated, so as to form cavities called *ventricles*. Of these cavities anatomists have enumerated four, sometimes five. The two nearest the upper surface are called *lateral ventricles*, as they lie on each side of the middle *callous portion*, and are separated by a thin pellucid double partition, which terminates below in an arch covering the third ventricle. The fourth is more deeply situated, and farther back. On what is called the *floor* of the lateral ventricles, are several prominences that have received particular *names*, especially *optic thalami*, or apparent origin of the optic nerves, and two long vascular bodies which approach each other towards the fore-part, where they pass through a hole leading to the cavity below. All these cavities communicate with each other, and are often found containing a watery fluid. A little behind and below the lateral ventricles are found five remarkable protuberances, one of which is the *pineal gland*, which was formerly supposed by philosophers to be the seat of the soul.

The *dura mater* is composed of two layers, and forms numerous cavities within its doublings. These are called *sinuses*, and in the living body are filled with blood. One is situated longitudinally at the top of the head, the *superior longitudinal sinus*, and one on each side of the body of the sphenoidal bone, the *lateral sinuses*.

The size of the human brain varies in different individuals, but, in general, it is proportionally larger in a young person than in an adult. The largest brain of an adult man weighs about four pounds, and the smallest about two pounds and a half. On a medium calculation, the human encephalon bears to the size of the whole body the proportion of one to twenty-seven. Of the whole brainy mass, the brain, properly so called, is about nine times the size of the cerebellum; and, of these nine parts, about six are occupied by the hemispheres, or general substance, while the rest comprehends the part more immediately connected with the nerves.

The *spinal marrow* is that substance continuous with the oblong portion of the encephalon, which fills the canal formed by the junction of the large central holes in the vertebræ of the spine. It is similar in structure to the encephalon, except that the whiter part of its mass is exterior, and it is enveloped in similar membranes. Towards its lower, or sacral extremity, it is divided into numerous fibres, supposed to resemble a *horse's tail*.

Connected with the encephalon and spinal marrow, but whether arising from these or terminating in them we shall not determine, as these are disputed points, are numerous white pulpy cords, of very different sizes, and most of them connected with each other, either by cross filaments, or rounded, enlarged portions, called ganglions. These are the nerves, and they appear in pairs, one on each side of the encephalon and spinal marrow. They are surrounded by membranes, similar to those of the general brainy mass, except at their minute ramifications.

There are generally reckoned ten pairs of nerves connected with the encephalon, and passing through the holes that are seen in the base of the skull. The two that are most forward are undivided, and pass to the nose through the holes of the ethmoidal bone. These are called the *olfactory* nerves, or nerves of smelling. Immediately behind these are two larger nerves, which meet each other, apparently unite their substance, and pass separately, one to each orbit, to be distributed on the interior of the ball of the eye. These are called the *optic* nerves. The third and fourth nerves also enter the orbits and supply the muscles of the eye-ball. The fifth pair consists of three bundles, of which one goes to the orbit, a second supplies the greatest part of the upper jaw or face, and the third the lower jaw. The sixth pair is distributed chiefly on a particular muscle of the eye-ball. The seventh pair, or what by some is called the first portion of the seventh pair, supplies the internal cavity of the ear, and is thence called auditory nerve. The eighth pair, or second portion of the seventh, is distributed externally on various parts of the face, and is thence called facial nerve. The ninth pair, according to some the eighth, is chiefly distributed on some of the important organs of the chest and belly. The tenth pair, by some called the ninth, is distributed on the tongue and organs of speech, and is called *lingual* or *hypo-glossal.*

Thirty principal nervous trunks are immediately connected with the spinal marrow on each side, passing through holes in the interstices of the vertebræ. Of these spinal nerves, the three highest supply the sides of the neck and head; the five next unite together in a large *plexus* or net-work, and afterwards form a considerable trunk that is branched out on the atlantal extremity; the twelve next supply the spaces between the ribs; and five, or, according to some writers, seven, between the ribs and *sacrum*, conspire to form two considerable trunks that supply the sacral extremity and parts adjacent.

Besides these, there is a very important nerve, or series of communicating nerves, called the great *sympathetic*, formed chiefly by a nervous cord extending from the head to the sacrum, passing on each side through the neck, chest, belly, and pelvis, and communicating, through the medium of *ganglions*, *plexuses*, and nervous filaments, with almost all the nerves of the body.

We have seen that all the vertebral animals have an encephalon; but this is very different in its structure and proportion in the different classes. The brain of the *mammalia*, indeed, nearly resembles that of man; and in a few instances, as in the ape tribe, is nearly as large in proportion to the body. In most quadrupeds, the anterior lobes of the brain are lengthened out into processes, terminated by the olfactory nerves, and in many instances the partition formed by the dura mater between the brain and cerebellum assumes a bony texture. The convolutions on the surface of the brain are often less numerous than in man, and the proportional size of the cerebellum is considerably greater.

In the cetaceous animals the brain is generally smaller, in proportion to the body, than in quadrupeds; but its substance is denser and more evidently fibrous, and the distinction between the cineritious and medullary substance is extremely well marked. The lateral ventricles and optic thalami are proportionally large. The spinal marrow in these animals is very small.

The brain of birds is often larger, in proportion to the body, than in man and quadrupeds, but it is very differently formed. It is smoother in its surface, and the optic thalami, instead of being within the lateral ventricles, lie behind and below those cavities forming a part of the lower surface of the brain. The *dura mater*, too, in this class, is scarcely ever produced between the hemispheres, and there is no callous central portion, or annular tubercle, and probably no pineal gland.

In reptiles and serpents the brain is small and simple, consisting of five roundish eminences, two hemispheres, two nervous thalami lying behind them, and a simple cerebellum, that exhibits no appearance of the arbor vitæ. The dura mater forms no processes. In these animals, however, the spinal marrow is, proportionally, much larger than in the superior classes.

In fishes the brain is very small, and does not fill the cavity of the skull. It is constructed in a manner similar to that of reptiles, and is surrounded by a simple undivided *dura mater*. In most of these animals the trunks of the optic nerves evidently cross each other.

The common centre of the nervous system, or common *sensorium*, as it has been termed, consists in *crustacea* and *insects*, of a medullary cord, interspersed with knots, or ganglions, running through the body, and being generally a little larger towards the head. In the *larvæ* of some insects this enlarged part is double, and is supposed to resemble a brain.

In some *mollusca*, as the cuttle-fish, the nervous cord is double from the head downwards. In *worms* it resembles that of the larvæ of insects.

The nerves of *quadrupeds* nearly resemble those of man, except that they are larger in proportion to the brain. In *cetaceous* animals the *olfactory nerves* are wanting. In the inferior classes, the nervous trunks are less numerous and more simple, as we descend to *zoophytes*, in which no such cords appear.

The brain is allowed on all hands to be the centre of sensation and of intellect. These faculties, however, do not keep pace with each other. Many of the inferior animals excel man in the acuteness and delicacy of some of their senses. The scent of the hound, and the sight of the eagle are proverbially superior, and it is probable that the *taste* of many animals is more discriminating, if not more delicate than ours. But no animal, not even the elephant, can rival man in his intellectual powers, and none possesses like him the rational faculty of speech. To what is all this owing?

We have already hinted at a division of the common sensorium, into that part which occupies the upper and middle parts of the skull, and that which lies upon the base, and gives out or receives the nerves, and have stated, that, in many, the former is at least twice as large as the latter. If we suppose with Soemmering, that the former portion is the centre of intellect, and the latter that of sensation, we may conclude that, all other things being equal, the measure of intellect or mind possessed by an animal, is to be estimated by the proportional size of the upper part of his brain. Man exceeds all other animal in this respect; and we find that in proportion as he approaches the inferior animals in the lowness of the forehead and the flatness of the crown, the more he descends in the degree of intellectual powers.

Respecting the offices which the common sensorium performs in the animal economy, we are still very much in the dark. That the brain is a secreting organ, forming a peculiar fluid that is conveyed along the nerves, and therefore called the nervous fluid, is at least highly probable, and that through this organ we receive from without, and exercise the several voluntary functions of the body, is generally allowed; but how these communications take place, and especially how mind is connected with body, we never have been, and perhaps in this state never shall be, able to determine.

There are, however, certain established facts or principles respecting the physiology of the nervous system, which it is necessary here to notice. Thus, we find that the nerves which supply the organs of the senses communicate immediately with the brain, while those which supply the organs of voluntary motion communicate more directly with the spinal marrow; that when pressure is made upon a nerve, a numbness, and loss of motion or of action in the part to which the nerve leads is the consequence; that when pressure is made on the spinal marrow, all the parts below the seat of the pressure have their sensibility and mobility diminished or destroyed, and that pressure on the brain itself is attended with more or less of general torpor and paralysis. It is probable that the real seat of sensation is the brain, or centre of the nervous system, though we commonly refer the sensation to the extremity of the nerve most remote from the sensorium, as when a person who has lost his leg occasionally feels pain at the stump, which he refers to his toes.

Various sympathies which take place in the animal economy are explained from the connection of nervous filaments. Thus, when we know that branches from the fifth pair of nerves supply the nostrils, the scalp, and the eyes, we shall not be surprised that violent scratching of the head, as with a sharp comb, produces sneezing, and that the sudden inhalation of pungent odours excites a copious secretion of tears.

An intimate connection is found to subsist between the nervous and the muscular systems. Thus children and delicate people, who possess unusual sensibility, have also a more irritable muscular fibre, or are more subject to spasmodic and convulsive diseases. Again, whatever increases the sensibility of the muscles, increases also their irritability, and *vice versa.*

It has lately become fashionable to explain the temper, dispositions, virtues, and vices, both in man and inferior animals, from the prominences of the brain, as shewn externally, by the corresponding inequalities of the skull. A person whose head is unusually prominent at its upper middle part must be remarkable for piety; one whose skull projects more than is ordinary above the ears, is disposed to murder his fellow creatures; and one who has the fore-part of his temples more than usually developed, as it is termed, is more witty than his neighbours. Notwithstanding all that has been written and asserted by Messrs Gall and Spurzheim, and their followers, we cannot help believing, that there is more of fancy than reality in this doctrine, and that a great addition of observation and experience is required before we can judge successfully of either our human or brute fellow-creatures from the prominences of their skull more than from the diversity of their features.

SECT. II. *Of the External Senses.*

Physiologists have agreed in limiting the number of the external senses to five, though of late it has been supposed that some animals possess a sixth. The most generally diffused of all these senses appears to be that of *feeling.*

The lowest orders of animals are evidently susceptible of impressions, and probably have a sense of pain and pleasure, though in a degree very inferior to those which possess a visible nervous system. We would say that these animals possess *sensitivity,* but not *sensibility*; and in this respect polypes and other zoophytes are raised but one step above the vegetable kingdom.

Feeling.—The organs of feeling are either general or particular. The general organ, in almost all animals, is the skin, and more particularly that part of it on which the nerves terminate, called the *papillary portion.* To avoid repetition, we shall not at present describe even the human skin, but shall treat of it with the other integuments among the organs of *Integumation.*

The particular organs of feeling are, in man, the hands, and more especially the points of the fingers, which, in some persons, acquire such a delicacy of sensation, as to enable them to read by feeling the impressions made on paper by the types of a printing press. It is probable that the toes have also naturally a considerable nicety of feeling, though in most persons their sensitive power is blunted by pressure and want of habit. We know that young children commonly employ their toes in grasping a finger, or similar object; and those who are without hands employ their toes very successfully as substitutes for those important organs.

Only those quadrupeds called *quadrimana,* including apes and lemurs, appear to employ their fore-paws as organs of feeling, but many of them possess organs of very delicate feeling power. Thus, the trunk of the elephant is able to perform even the nicer actions of the human hand. With this organ the animal unties knots, draws bolts, and we have seen one of them take up a sixpence from the ground, holding it between the lip and margin of its trunk. The lengthened snout of the *rhinoceros* and the *tapii,* seem to answer the same purposes in a less degree. Many quadrupeds have whiskers, by means of which they appear to judge of the diameter of holes through which they have to pass.

In birds, the bill, which is well supplied with nerves, is supposed to be one of their most delicate feeling organs, more especially in those that seek their prey in shallows, or among the mud.

What particular feeling organs are exercised by reptiles we have few means of discovering. In many of them, especially those whose bodies are covered with shells or scales, the sense of feeling cannot be very acute; but it is certain that frogs, toads, and similar soft reptiles, readily perceive the contact of other bodies and it is probable that the feet of the tree-frogs are sufficiently sensible of touch.

Among fishes the lips and the *cirrhi,* or *tentacula,* which project from them in many species, appear to be the principal feeling organs.

In *crustacea* and *insects,* there are two organs, either or both of which may be the instrument of feeling, the *palpi,* commonly called the feelers, and the *antennæ.*

The *tentacula* of mollusca and worms, and the arms of cuttle-fish, star-fish, and polypes, must be considered organs of feeling, as well as means of taking their prey.

By feeling we judge of the roughness or smoothness, hardness or softness, figure, temperature, and other tangible properties of material substances. For the complete exercise of this sense, it is necessary

Sensation.

that the *papillæ* of the skin be soft and flexible, and that the cuticle which covers them be soft and thin.

Tasting.—Tasting is the sense which seems most nearly allied to feeling. Its organs are chiefly the tongue and the palate, though, in some instances, the taste of sapid bodies is not perceived till they have passed these organs, or is most evident in the gullet or the stomach.

The tongue, even in man, is an organ destined to many different purposes, and, on the whole, tasting is not one of the most important. We shall, however, complete our description of it in this place. The human tongue is composed partly of muscle and dense cellular substance, and partly of numerous nervous *papillæ,* of different forms and sizes. Besides its proper muscular fibres, constituting the lingual muscles, there is a considerable irregular mass of flesh above these, and immediately below the nervous *papillæ.* Both the upper and under surface of the tongue is covered with a smooth mucous membrane, below which lies a texture similar to what we shall afterwards describe as one of the *integuments,* consisting chiefly of a net-work of minute vessels, and within this again is the proper skin of the tongue, abounding, especially on its upper surface, with nervous and mucous *papillæ.* What are regarded as the mucous *papillæ* are arranged towards the root of the tongue, where they form an angular groupe, diverging from a point next the root towards the fore part and sides of the tongue. They are of a spherical or oval figure. The nervous *papillæ* occupy about two-thirds of the tongue towards the tip. Some of them are like tubercles, with a narrow neck of a whitish colour, pretty large, but few in number; others are conical, pointed, small, and numerous. These papillæ appear to constitute the immediate organ of taste.

The bony palate already described is covered with a dense, thick, mucous membrane, smooth next the mouth, adhering strongly to the bones, with intermediate mucous and nervous papillæ. From its back part hangs a membraneous curtain, commonly called the *soft palate,* having an oblong glandular body, called *uvula,* hanging from its middlemost depending part, and two other glandular bodies, called *tonsils,* or almonds, connected with the lower part of the membrane at its sides.

Connected with the tongue at its lower part are two glands on each side; one pair, called *sublingual,* as lying immediately below the tongue on each side of the *frænum,* or vertical membrane, that ties down the tongue to the parts beneath; and the other pair called *submaxillary,* attached to the inside of the lower jaw, below the sockets of the teeth. There is another pair of glands called *parotid,* lying one before each ear, and communicating, as well as the two former, with the cavity of the mouth, by hollow tubes or *ducts.* All these glands are called *salivary,* because they secrete the *saliva,* or slaver, a transparent, watery, tasteless fluid, so far necessary to the sense of tasting that all solid bodies must be more or less dissolved in it before they can affect the nervous *papillæ* that constitute the immediate organs of taste.

Hence those substances are in general most sapid which are most easily soluble in the saliva, as acids, salts, sugar, &c.

Though the tongue be regarded as the essential organ of taste, it is certain that the palate materially assists in this sensation, as we find that tasting becomes more exquisite when we press the tongue with the sapid body on it against the roof of the mouth.

The comparative anatomy of the organs of taste is very obscure. We know that almost all the vertebral animals, and many of the invertebral, have a tongue; but in most of them the structure of that organ is such as to fit it rather for the act of swallowing than the sensation of taste. Most of the quadrupeds, indeed all the cetaceous animals, many of the reptiles and serpents, and some of the fishes, have a soft moist fleshy tongue, provided in a greater or less degree with nervous *papillæ*; but as many of these animals swallow their food without chewing, it is probable that in these cases the sensation of taste is very slight. Very few birds, as parrots, and some predacious and water birds, have a soft thick tongue, provided with nervous *papillæ,* and moistened with saliva; but in general, the tongue of birds is horny, stiff, and dry, and supplied with few nerves.

It is probable that the hinder pair of *palpi,* or feelers, in several insects, possesses in some degree the sensation of taste. What is called their tongue seems to be merely intended for taking food.

Smelling.—The immediate organ of smelling appears to be that highly vascular and nervous membrane called by anatomists *pituitary,* which lines the nostrils and adjacent cavities.

The nose in man consists partly of several bones of the skull and face, which articulating together form the walls or sides of the nostrils and part of their internal contents, partly of cartilage, and partly of skin and muscle. The upper part of the nose is formed by the *frontal* and *nasal* bones in front; the *upper maxillary, ungual,* and partly the *sphenoidal,* on the sides; the *sphenoidal* on the back part; the *upper maxillary* forming the base or floor of the nostrils; the *ethmoidal* constituting the greatest share of their upper internal part, and a portion of the long partition that separates the nostrils, with the *spongy* bones hanging on each side, while the rest of the partition is formed by the *vomer,* and a thin cartilaginous expansion extending between this and the *ethmoidal* bone. The lateral parts of the nostrils below the *nasal* bones are formed of a thick, soft, flexible cartilage, covered on the outside with a dense skin with numerous pores.

The nostrils communicate above with the *frontal sinuses,* (or two cavities formed by the separation of the outer and inner plates of the frontal bone in the lower part of the forehead,) behind and below with the mouth, and with the *sphenoidal* sinuses; and at the sides, a little backwards, with the *sinuses* in the *superior maxillary* bones. All these communicating cavities are lined with one continuous *pituitary membrane,* and the same membrane covers the spongy bones within the nostrils and the ethmoidal cells. The surface of this membrane is kept moist by the continual secretion of a mucous fluid, which is increased by the action of irritating substances received into the nostrils during inspiration.

The medium through which odours impart the sensation of smelling is the air, which being inhaled through the nostrils during inspiration, carries with it those minute particles which are continually flying off from odorous bodies, and which are commonly called *effluvia*. If these effluvia be very irritating, they excite sneezing, which consists in a sudden and violent expiration, for the purpose of dislodging the offending matters, the effects of which are also counteracted by the increased secretion of *mucus*.

The organs of smelling in the inferior animals are essentially the same as those in man, but differ considerably in structure and complication in the several classes and tribes. Those quadrupeds which we know to be remarkable for the nicety of their scent, as dogs, cats, bears, and weasels, and several others which we judge to be so from analogy, as the elephant, the hedge-hog, the mole, and the ruminating quadrupeds, have the nasal cavities either very large or very complicated.

The *cetaceous* animals having no *ethmoidal* bone, and no peculiar *olfactory nerves*, are supposed to be very defective in the sense of smelling.

Nor does this sense appear to be very acute in *birds*, as their nestrils are in general small and contracted. The same may be said of *reptiles* and *serpents*.

Fishes, considering the element in which they live, which appears capable to a certain degree of communicating odours, are more remarkable than the two preceding classes for the structure of their smelling organs. Most of them have double nostrils on each side, and their pituitary membrane is elegantly disposed in semicircular folds.

It seems an undoubted fact, that most *insects* possess the sense of smelling, but the organs by which they excercise this sense have not been satisfactorily ascertained.

Hearing.—The organ of hearing is situated in and about the *temporal bone*. It consists partly of internal and partly of external parts, though, in a great variety of animals, the latter are either wanting or extremely imperfect. The external parts are peculiarly fitted for receiving the pulsations of the air by which sounds are produced, and conveying them to the internal cavities, where they are propagated or reverberated, so as to excite the sensation of hearing.

The external ear in man consists chiefly of a cartilaginous substance, variously contorted, covered with skin, and provided with numerous muscles, though in most persons the cartilage is scarcely susceptible of motion. The prominences and depressions of the cartilaginous auricle have received different names, according to their supposed form or their situation. The outer rim is called *helix*, and the inner rim immediately contiguous to this *anti-helix*, and the depression between these two, at the upper part, is called *scapha*, or the boat. The eminence below the upper and fore part of the *helix*, next the face, is called *tragus*, from its being sometimes covered with hair like a *goat's beard*; and the lesser eminence, nearly opposite, in which the *anti-helix* seems to terminate below, is called *anti-tragus*; the depending soft skinny part is the *lobe* of the ear.

From the auricle there is a winding cartilaginous passage, lined with a delicate skin, between which and the cartilage are numerous glands, secreting a thick fatty substance, called the wax of the ear. This winding cavity terminates in a circular bony rim, filled with a firm elastic membrane, resembling parchment, called the membrane of the drum of the ear.

Here properly begins the *internal ear*, which is of a very complex structure. In the first place, there is a small cavity behind the membrane just mentioned, called the drum of the ear, which contains four small hard bones, and has several openings. Two of the bones are connected with the membrane of the drum, and are closely articulated together. One of these is called the *hammer* and the other the anvil. This latter has two processes, of which the shorter is contiguous to an opening leading to cells in the *mastoid* process, while the longer is articulated through the medium of a very minute round bone with the fourth bone, named from its shape the *stirrup*. The openings from the drum are one forwards towards the mouth, into which it opens by a cartilaginous tube called the *eustachian* tube, and two openings inwards, one of which is filled up by the *stirrup* and the other by a membrane.

More internally behind the drum is another cavity, called, from its complexity, the labyrinth. This labyrinth is composed chiefly of three circular hollow passages, within the substance of the bone, called the semicircular canals, and a double spiral cavity, which, from its resemblance to a snail's or periwinkle's shell, has been termed *cochlea*, all communicating with a common central cavity. Through these winding passages are distributed branches of the *auditory nerve*, and the rest of the cavity is filled with a gelatinous fluid.

The vibrations of the air, generated by sounding bodies, being received by the broad expanded hollow of the external ear, are conveyed through the winding passage to the membrane of the drum, on which they strike, and set in motion the little bones behind. These again communicate the pulsations to the gelatinous fluid within the labyrinth, by means of which the auditory nerve becomes affected, and excites in the brain the sensation of sound. Sounds are also partially communicated through the mouth, by means of the *eustachian tube;* for when this tube is obstructed hearing becomes imperfect.

Internal organs of hearing are found in all the vertebral animals, and in a few of the invertebral. Many of the former division also possess external organs more or less perfect; but what are properly called *auricles*, or external ears, are found only in quadrupeds.

We know of only four tribes among the *mammalia* that want the external ears; but this is the case with most seals, walrusses, the mole, and the duck-billed animals. In many quadrupeds again, as the common bat, the elephant, the fennec, the squirrel, and the ass, the ears are remarkably large. The structure of the internal ear in quadrupeds is similar to that which we have described in man.

The cetaceous animals have only a small external auditory passage, and the bony part of their internal ear is but loosely connected with the skull. They have, however, a large eustachian tube; but all the parts of the labyrinth, especially the semicircular canals, are remarkably small. Yet these animals seem

Sensation.

to hear well; a circumstance which is probably owing to the superior power that water possesses of conducting sounds.

In birds there is commonly a very regular arrangement of the feathers round the openings that lead to their internal ears, and their cavities are connected together by air cells passing round the skull, and the eustachian tubes have a sort of common opening in the arch of the palate. These animals have no *cochlea.*

Of the reptile tribes, only the crocodile has any thing like an outer auditory passage. In the rest, the membrane of the drum is either level with the skin, or immediately below it. In some of them the eustachian tube is wanting, and the internal ear is, in other respects, very imperfect.

The organ of hearing in fishes consists chiefly of three large canals, and is farther distinguished from that of the superior animals by its increasing in size according to the age and growth of the animal; whereas in the other classes which we have mentioned, the internal ear is fully developed at a very early period of existence.

Among the crustaceous animals, the cancer tribe have an evident internal organ of hearing, situated on each side at the root of the *palpi*, with a small bony tube by which it communicates with the water.

If we except the cuttle-fish and the animals just mentioned, we know of no invertebral animals that have manifest auditory organs, though it is probable that many of them can distinguish sounds.

Seeing.—The eye and its appendages, constituting the organ of *vision*, merit particular attention. The ball of the eye is encased in a bony cavity, where it is securely lodged, and through the back part of which it communicates with the brain.

In man, and those animals which resemble him, the cavity of the orbit is composed of seven bones, of which the *frontal bone* forms its upper part, or roof, the *upper maxillary* the greater part of its floor, the *sphenoidal* and *malar* its outer sides, and the *ethmoidal* and *ungual* the greater part of its inner side, while the *palatal bone* forms a small portion of its lower part within. In its general form it is conical, having a large opening in front, surrounded with a strong bony ridge, and drawing nearly to a point within. It is lined with *periosteum* and fat.

Round the outer bony circle of the orbits is attached the *orbicular muscle* that forms the fleshy part of the eye-lids, the rest of these curtains being composed of loose skin and cellular membrane, and terminated at their edge by an arched cartilage, called *tarsus*, supporting the eye-lashes, and having a number of minute orifices that form the outlets of minute glands; and not far from the inner corner of the eye are two more remarkable orifices, one in each eye-lid, from which proceed two canals, meeting at the inner corner, and leading to the nose. These form the lacrymal points and ducts that carry off the superabundant tears into the nostrils. That part of the upper eye-lid which supports the eye-brow, is provided with thicker cellular substance; and the inside of each lid is lined with a very fine, soft, and delicate membrane, which, being reflected over the greatest part of the front of the eye-ball, forms what is called the white of the eye.

Sensation.

The eye-ball is composed principally of three or four membranes called *coats*, and three fluids, of more or less density, called *humours*. The outer coat is dense and fibrous, and, being of a firm texture, is called *sclerotic*, or hard coat, and covers about four-fifths of the eye-ball. The remaining fifth, forming a small spherical prominence in front of the ball, is protected by a pretty thick transparent part, closely united at its edge to the sclerotic, and called *cornea*. Within the sclerotic coat is another called *choroid*, composed of numerous convoluted blood-vessels, and lined with a dark opaque mucous matter, called by anatomists *pigmentum nigrum*. Within this again is a very delicate nervous expansion, evidently proceeding from the trunk of the optic nerve, which is considered as the third coat of the eye, and called *retina*.

The interior of the eye-ball may be regarded as composed of three cavities, each lined with a peculiar membrane, and containing fluids of very different densities. By far the greater portion, including all the back part of the ball, is filled with a fluid very much resembling, in colour and consistence, the white of eggs before it is coagulated. This is called the vitreous, or glassy humour. It has a circular concave depression in the middle of its anterior part, in which lies a body of a double convex figure, but flatter on its fore part, and of much greater density than the vitreous humour. It is inclosed in a thin transparent membranous capsule, and, from its form and transparency, is called *crystalline lens*. Its margin is surrounded with a plaited membrane, attached to the vitreous humour, and called *ciliary plicæ*. The remaining part of the eye-ball in front of the lens is filled with a clear watery fluid, thence called the *aqueous humour*; but this cavity is divided into two unequal portions, called the *anterior* and *posterior*, by a broad circular coloured membrane, extremely vascular, called the *iris*, with a central circular opening, capable, in the healthy state of the eye, of contraction and dilatation, called the *pupil*.

If we suppose a line drawn through the centres of the *cornea*, the *pupil*, and the *crystalline lens*, it will form the axis of the eye-ball. Now the part where the trunk of the optic nerve communicates with the eye-ball is not in this axis, but on the side of it next the nose, and its entrance is marked by a small spherical prominence projecting within the eye. Nearly at the posterior extremity of the axis there is a small spot on the choroid coat, of a yellowish colour, and not covered with the expansion from the optic nerve, so that the *retina* appears here to be perforated.

The eye-ball is nearly enclosed in four straight muscles, which, acting separately, move it upwards, downwards, to, or from the nose, but, acting together, press it backwards, and probably flatten it. There is a peculiarity of structure in the course of the *superior oblique muscle* that deserves to be noticed. Its tendon passes through a perforated cartilage, attached to the inner or nasal side of the orbit, and forming a pulley on which the tendon moves, so as to alter materially the direction in which the fibres of the muscle would act were it not for this contrivance; hence this has been called the *trochlear muscle.*

In the upper part of the orbit, between the eye-

Sensation. ball and periosteum, on the temporal side, is a compound glandular body, whose office is to secrete the tears, whence it is called the *lacrymal gland*. From it there pass several tubes through the substance of the upper eye-lid, and opening towards the cornea, and through these the tears continually exude, and are spread over the eye by the motions of the upper lid.

The immediate organ of vision appears to be the *retina*; for when the optic nerve is rendered insensible, as in the disease called *amaurosis*, though every part of the eye-ball is in a sound state, vision is destroyed; and experiment has proved that no sensation of vision is produced on that yellow spot we have mentioned at the bottom of the eye where the *retina* is deficient.

Vision is produced by the rays of light, which, entering the eye through the transparent *cornea*, are variously refracted in passing through the *aqueous humour, crystalline lens*, and *vitreous humour*, and strike upon the *retina*. As the rays of light come from various points of a visible object, and pass in straight lines to the pupil, they must cross each other; and we know that when an eye, taken from the body and properly prepared, by removing the *sclerotic* and *choroid* coats from its back part, is held at a proper distance from a luminous object, a picture of this object in an inverted position appears upon the *retina*. Hence it is natural to conclude, that the picture of visible objects formed by the rays of light on the retina of a living eye, are inverted, though habit and experience enable us to represent them to the mind in their natural position.

There is a certain distance, or *focus*, at which every object is most distinctly seen, but this distance varies in different individuals. Thus, a middle-aged person, with good eyes, can read an ordinary type most distinctly at the distance of about eight inches. A young person, or one that is near-sighted, requires the object to be much nearer the eye, and an old person sees best at a greater distance. The reason of this is, that in the former, at the medium distance, the rays of light are refracted too much, and meet in a point before they reach the *retina*; while in old people, or those who are called far-sighted, the rays are less refracted than usual, and do not meet in a point upon the *retina* unless the distance of the object is increased.

For perfect vision, it is necessary that the cornea, the crystalline lens, and the humours be perfectly clear and transparent, the pupil round, open, and easily susceptible of contraction and dilatation; that the *retina* be sensible to luminous impressions; and, in general, that the mucous pigment that covers the *choroid coat* be of a dark colour.

The great use of this pigment seems to be to absorb the rays of light, and prevent the confusion that would be occasioned by their reflection. This is peculiarly necessary in a strong light. Hence people, in general, whose pigment is black, and whose pupil readily contracts, see most distinctly in a strong light; whereas those who have weak eyes, or whose pupil is less sensible to the stimulus of light, see best when the light is moderate, as in twilight. This is also the case when the centre of the *lens* becomes opaque; for then, as the rays of light can pass only through the margin of the *lens*, it is necessary that the pupil should be considerably dilated before a sufficient number of rays can be admitted, and this in such eyes can happen only in a moderate light. Sensation.

Persons with light hair and light eye-brows and eye-lashes, have generally the pigment of a corresponding light colour; and those persons called Albinos have it of a reddish colour, as is the case with white animals among the inferior classes. None of these can bear a strong light, and the latter see distinctly with a very faint light. This also depends much on habit. Those who have been long shut up in a darkened room or dungeon, can at length distinguish objects which, on their first entering the apartment, were totally invisible.

Some persons, especially when young, have the *cornea* unusually convex, which occasions them to be near-sighted. The opposite infirmity is produced in old people by the flattening of the *cornea*, and the sinking of the eye within the orbit, in consequence of the absorption of some of the fatty matter with which the eye-ball is surrounded. The former defect is generally remedied by *concave*, and the latter by *convex* glasses. The circumstance of our seeing an object single with two eyes, though there is no doubt that an image of the object is painted separately on the retina of each eye, has not yet been satisfactorily explained. It is generally supposed to be the effect of habit; but even persons who have been born blind, and have their sight suddenly restored by a surgical operation, do not see objects double; while any person may, under certain circumstances, make himself see double, though generally accustomed to see in the usual way.

If we except one of the *mammalia*, the blind rat, one reptile, the *proteus*, and one fish, the *myxine glutinosa*, all the vertebral animals with which we are acquainted possess the sense of vision; for even the mole, which has often been represented as blind, has perfect, though very minute eyes. In all these classes, too, the eyes are always two in number, though in one of the inferior orders of insects there are animals which have six or eight eyes.

The eyes of the inferior animals differ much in proportional magnitude. Among quadrupeds, the mole and the shrew have proportionally the smallest eyes; but, in general, the magnitude of the eye-ball is in an inverse ratio to that of the animal. This holds true also in other classes. In the largest whale, measuring sixty or eighty feet in length, the eye-ball is not larger than a middle-sized orange. The eyes of young animals are also proportionally larger than those of the adult.

The eyes also differ in direction. Only the ape tribe have them directed forwards as in man; in all other quadrupeds, in birds, and most reptiles, they look sideways. In some reptiles, and in many fishes, the eyes are situated nearly at the top of the head, so that they are naturally directed upwards.

In general structure the eyes of quadrupeds nearly resemble those of man, except that the *sclerotic coat* is generally thicker and firmer, especially at its back part; that the *choroid coat*, at the bottom of the eye, is, in many instances, especially in those quadrupeds that play by night, of a brilliant colour;

Sensation.

that the *cornea* is often more convex and protuberant; that the *retina* is often evidently fibrous; and that the figure of the *pupil* is frequently of an oblong or oval form. Some quadrupeds, too, have a third eye-lid, or what is called a nictitating membrane, which draws over the *cornea* sideways, and defends the eye either from too much light or from external injury. This membrane is most remarkable in the cat tribe, the opossum, the seal, and the elephant. Few quadrupeds have eye-lashes.

The eye of cetaceous animals has the back part of the *sclerotic coat* thick and cartilaginous, while its fore part is thin and soft, and their *crystalline lens* is much more convex than that of man and quadrupeds.

The eyes of birds are generally very large, and lodged in ample, but usually shallow orbits. The *cornea* is very convex, and where it joins the *sclerotic* there is a bony ring formed of plates lying over each other. There is a peculiar organ in these animals called *marsupium*, or the purse, which passes through the *vitreous humour* from the *retina* nearly to the *crystalline lens*. It is an angular membrane, very vascular, and covered with a dark substance like the *black pigment*, and seems intended for absorbing superabundant rays of light. In birds, the lower eye-lid is larger than the upper; and in almost all of this class, the eyes are closed by raising the former. They have also a large nictitating membrane, moved by two peculiar muscles.

In reptiles, the eye is constructed much like that of birds, having a similar bony ring round the margin of the *sclerotic coat* in many of the species, and in general a nictitating membrane. Many of them, however, have no eye-lids, but only a transparent, immoveable curtain formed from the cuticle. This also is the case with serpents.

The eyes of fishes differ from those of other animals, in having the *crystalline lens* of a spherical figure, the *choroid coat* and *retina* composed of several *laminæ*, and in having a firm body, shaped like a horse-shoe, between the internal and middle layers of the *choroid*. There is also a membrane somewhat similar to the *marsupium* of birds.

Among the crustaceous animals there are several that have but one eye, but most of them have two, which, in some instances, are sessile, or close to the body, while in others they are *pedunculated*, or raised on a moveable footstalk.

Of the *mollusca*, only the cuttle-fish, under which we include the *sepia* and *octopus* tribes, and the snails and slugs, have proper eyes, which in the latter tribes are situated on footstalks.

Most insects have eyes, and of these the *arachnides*, or spiders, and similar animals, have from two to eight; while in some other insects, as the dragonfly, the exterior of the eye is composed of a vast number of small six-sided convex surfaces, each of which seems to perform the office of an eye.

Sect. III. *Of the Internal Senses and of Sleep.*

Certain affections of the mind, which seem to depend on the action of the brain, as *memory*, *imagination*, *judgment*, have been called the *internal senses*. Although the consideration of these belongs properly to metaphysics, it may be expected that we should briefly notice them here.

Of the internal senses, *memory* is the most general among animals, and that which appears to be the soonest developed. A very considerable number of the inferior animals enjoy this faculty in common with man, and many of them apparently in an equal degree. The *dog*, the *horse*, and the *elephant*, are instances familiar to every one; and indeed all those animals that are susceptible of domestication show evident proofs of memory. The *parrot* remembers the lessons he is taught; the *canary bird* whistles correctly the tune he has acquired; the *tortoise* hobbles to meet the hand that is accustomed to feed it; and even the *toad* resorts to the spot where it receives its daily food. It is probable that in most animals memory is confined to what has been called *reminiscence*, or the *passive remembrance* of past events, though man is not the only animal capable of *recollection*, or the faculty of *recalling former ideas and perceptions*. When the dog, after an absence of some months or years, sees a person with whom he was formerly intimately acquainted, he usually looks and smells for some time before he recognises his former friend; and when he is satisfied of his identity, suddenly breaks out into rapturous expressions of joy at his return. In this case we think he exhibits proofs of *recollection*; and such proofs are occasionally exhibited by some other of the nobler quadrupeds.

The faculty of memory, as far as respects *susceptibility*, is strongest in childhood; but the mind is more *retentive* in youth and manhood. As age increases, the susceptibility of the memory declines; and an old man, who can readily remember the transactions of his boyish days, often finds it difficult to recollect the occurrences of yesterday.

Memory evidently depends much on the state of the body, and particularly on that of the nervous system. A fever, or a stroke of apoplexy, terminating in palsy, sometimes completely oversets the memory, and erases from the mind all traces of former ideas. A fit of intoxication has the same effect as to the events that took place during this temporary derangement of the mental powers.

Imagination, as far as we can conceive, is confined to *man*; though it differs in degree or vivacity in different individuals of the human species. It is generally most lively in youth; being not yet formed in early childhood, and subsiding with the advance of age. It does not seem to depend so much as memory on the state of the body, except that, in certain diseases, it becomes more lively, in others more or less depraved.

The faculty of *judgment*, as it depends on the exercise of reason, is certainly most remarkable in the human species; but is, we are satisfied, by no means the exclusive privilege of man. That *dogs*, *elephants*, *horses*, *cats*, compare, discriminate, and judge, cannot be doubted by those who have studied the natural history of those animals.

Unlike the two former faculties, judgment increases with age, at least till that period of dotage arrives when all the human faculties begin to sink into oblivion. This faculty never varies with the state of the body. In some diseases it is depraved,

Sensation.

in others nearly destroyed. Indeed, it is intimately connected with memory, and of course undergoes corresponding changes.

As connected with the nervous system, physiologists have also considered the *passions*. These, in a physiological point of view, are divided into the *exciting* and *depressing*. Of the former, the most remarkable are *hope*, *joy*, *love*, *desire*, *anger*, and *rage*; of the latter, *envy*, *jealousy*, *fear*, *grief*, *terror*. The exciting passions quicken the circulation and respiration, increase the animal heat, propel the blood to the head, and, when in an extreme degree, produce phrenzy, apoplexy, or death. The depressing passions act more on the nervous than the circulating system, though some of them, too, quicken the circulation. In their highest degree, especially when acting suddenly, they induce fainting, palsy, or death, from a sudden cessation of the motion of the heart.

Sleep forms another subject connected with the physiology of the nervous system, and is generally regarded as an affection of the mind.

The alternate states of watchfulness and sleep seem necessary in the economy of all animals; but the degree and manner of repose by sleep are very different. Some animals, as *reptiles*, and a few *quadrupeds*, appear to pass the greater part of their lives in a state of sleep, or torpor resembling sleep, while many of the human species scarcely occupy a fourth part of their time in this state of inactivity. The degree of sleep, however, depends much on age and habit. The younger the animal, the more sleep is necessary; and those who pass a life of indolence, sleep much more than the active and laborious.

The darkness of night, as it naturally invites to sleep, by withdrawing the objects of the senses, forms the natural season of repose to most animals. Some, however, as beasts and birds of prey, are most watchful during this period, which they employ in hunting.

The *attitude* in which animals sleep is also different. Many of them lie in a recumbent posture, as *man* and *quadrupeds*; some sit perched on a twig, or similar object, as most birds; others of the feathered tribes sleep standing on one leg; a few, as *bats*, hang suspended by the hind legs; and several fishes, and other marine animals, lie motionless on the surface of the water.

During sleep the voluntary animal powers are suspended, and the senses lie inactive, though some of them, as hearing particularly, are capable of being excited without banishing sleep. The *involuntary* actions, as circulation and respiration, are continued, but are slower than in the waking state. The imagination too, is generally very active, as appears from *dreaming*.

The immediate *cause* of sleep is supposed to be the exhaustion of what different physiologists call the *irritability*, *excitability*, or *sensorial power* of the system. It is evidently connected with a diminution of the *nervous energy*.

The subject of *dreams* being rather *metaphysical* than *physiological*, belongs to a different subject; but that of *torpidity* we shall consider after describing the phenomena of *respiration*.

Digestion.

Chap. III. Of Digestion.

Nature points out to all animals the necessity of repairing the waste of the body that is constantly going on by the appetites of *hunger* and *thirst*. There are indeed many animals, especially among the reptiles, that can endure abstinence for days, weeks, or even years, (see Abstinence;) and one among quadrupeds, the camel, can travel for several days without a fresh supply of drink; but all these animals bow at length to nature's laws, and perish if the supply of food or drink be too long delayed. There is perhaps no animal that bears hunger and thirst less easily than man; but man is the creature of habit, on which these appetites materially depend.

The younger the animal, the more frequent and imperious are the calls for food. This is evidently owing to the growth of parts, and the progressive evolution of the whole body, which is continually going on during the early stages of life. When the body has acquired its full growth the demands for nourishment are less urgent; and as age increases, both the appetite for food and the power of digestion generally diminish.

As all animals do not live on the same kinds of food, they are divided into three classes, according to the nature of their aliment. Those which live entirely on vegetable food are called *herbivorous animals*; those whose diet consists entirely of animal substance *carnivorous*; and such as feed equally or indifferently on both are denominated *omnivorous*. Perhaps man is the only animal that is naturally omnivorous, though many animals may be compelled by hunger, or taught by habit, to subsist on food to which their digestive organs are not naturally adapted.

Stages of digestion.—The general function of digestion consists of several stages. In the vertebral animals the food is first received into a mouth, where, in some cases, it is chewed or *masticated* by means of teeth, and mixed with *saliva*, while in others it is swallowed whole. From the mouth it passes through the gullet, by the act of deglutition, whence it is received into a stomach where it undergoes solution, and forms a crude mixture called *chyme*. This being received into the small intestines, and mixed with other fluids, forms *chyle*, which is gradually taken up or *absorbed* in the manner to be afterwards explained, while the superfluous, noxious, or excrementitious part is carried off by the large intestines, and finally expelled. Hence we divide digestion into *mastication*, *insalivation*, *deglutition*, and *chylification*.

Sect. I. *Of Mastication and Insalivation.*

The *organs* subservient to these stages of digestion are, the mouth, with its contained organs, the teeth, and tongue.

Mouth.—The cavity of the mouth is composed partly of hard and partly of soft parts. The hard parts are the jaws or *mandibles*, the *palate*, and the teeth, where these are to be found. The soft parts are the lips and cheeks externally, and the soft palate and gums within. The jaws and palate have already been described.

Variety of teeth.—Many animals are without teeth. This is the case with *ant-eaters*, *manes*, *armadillos*, and the *duck-billed animal* among quadrupeds; with the *balenæ*, or proper whales, among cetaceous animals; with all birds; with tortoises among reptiles; and with most invertebral animals. The teeth vary considerably in number, figure, and proportion, in the different tribes and classes of animals, but, in general, may be divided into three classes, *cutting teeth*, *tearing teeth*, and *grinding teeth*. The first are more or less flat and wedge-shaped, terminating with a cutting edge; the second are more or less conical, pointed at the tip, and often curved; and the third are broad and thick, generally terminating in several pointed protuberances, or a broad unequal surface. Some animals have only the second kind, and some only the first and third, and others only the second and third; only a few have them of all the three classes. This is the case with man and those quadrupeds which resemble him.

Structure of the teeth.—The teeth are generally composed of two parts, a body, and fangs or roots; the body being that which projects without the jaw, and the fangs those parts by which the tooth is fixed in its socket. The *cutting*, and generally the *tearing* teeth, have but one fang, but the grinders have several. In their intimate texture the teeth are formed of two substances, differing from each other in colour and consistence. The fangs, and part of the body of the tooth, are composed of bones similar to that which forms the skeleton; the rest of the body is formed of an extremely hard brittle white and shining substance, called *enamel*, which in some cases covers the tooth like an external shell, in others is intermixed with the bony part of the body of the tooth. The teeth are provided with blood-vessels, and probably with nerves, which pass through tubular hollows in the fangs.

An animal has not the same number of teeth in every period of its life. A certain number, called *temporary* teeth, make their appearance some time after birth; these are shed, and are succeeded by a greater number, which continue permanent.

In man there are twenty temporary teeth, which usually begin to make their appearance about seven or eight months after birth. They generally appear in the following order. Two of the front teeth in the lower jaw are first cut, and are soon followed by two in the upper jaw, and so on till the eight cutting teeth are produced. Then two of the *grinders* next the front are cut in each jaw, and after these the pointed teeth called *dog-teeth*, and in the upper jaw *eye-teeth*. These are followed by the rest of the grinders, till all the temporary teeth are produced, which generally happens within three years after birth. When the child is about six or seven years of age it begins to shed the temporary teeth, to make room for the permanent teeth, which are cut in much the same order as the former. They are generally 32 in number, and consist of eight front, or cutting teeth, four *canine*, or eye-teeth, four *bicuspidated*, or first grinders, and sixteen other grinders, the latest of which are sometimes called *wisdom-teeth*, as they seldom make their appearance till about the age of puberty.

Teeth of quadrupeds.—Of those quadrupeds that have teeth, the apes, lemurs, and bats nearly resemble man in their number and proportions. Those constituting part of Linnæus' *second order*, as the sloths, rhinoceroses, and elephants, have no cutting teeth in either jaw, while in the order *Feræ*, including most of the beasts of prey, there are numerous front teeth, but they are rather tearing than cutting teeth. The *glires*, comprehending, among others, porcupines, beavers, rats, and mice, marmots, hares, and rabbits, have two long and strong cutting teeth in each jaw, and a few grinders in the back part of the mouth, with large intervening spaces. The ruminating animals, including camels, sheep, deer, antelopes, goats, and horned cattle, have cutting teeth only in the lower jaw; while of the last order, *belluæ*, all have cutting teeth in the both jaws; and some, as the hog tribe and river horse, have the *canine* teeth prolonged into formidable tusks.

Of cetaceous animals.—The cetaceous animals that have teeth are chiefly the *cachalots*, or spermaceti whales, which have teeth only in the lower jaw, and the dolphin, porpus, and grampus, which have teeth in both jaws, all generally of the pointed tearing kind; but those called unicorn fish have a very long taper tusk (sometimes two) standing out from the muzzle. The proper whales have those peculiar horny plates, terminating in a hairy margin, improperly called whale-bone, which, though they answer not the purpose of mastication, serve to retain the food taken into the mouth.

Of birds.—Though birds have no teeth, many of them employ their mandibles for cracking seeds, &c. or for perforating the bark of trees in search of insects.

Of reptiles.—Among the reptiles all those called *sauriens*, comprehending lizards and similar tribes, have pointed cutting teeth in each jaw, and some have them in the palate. Frogs have teeth only in the upper jaw, salamanders in both, while toads have them only in the palate. Serpents have generally numerous sharp-pointed teeth in both jaws; and those which are venomous have sharp curved tusks in the upper jaw, that are perforated with a tubular canal, and connected with a bag containing a poisonous fluid, which, when pressed on by the tooth, suffers the poison to flow down through the tubular opening into the wound inflicted by the animal.

Of fishes.—The teeth of fishes are usually small but very sharp; but some of the larger tribes, as the shark, have them of a very formidable size and number, and attached to the palate as well as the jaws.

Crabs, &c.—Of the invertebral animals that have teeth, the principal are crabs, lobsters, sea-mice, leeches, sea-urchins, and star-fish.

Gums.—The gums are rather membranous than fleshy. They are very vascular, but, having few nerves, possess little sensibility. They serve to strengthen and support the teeth.

Cheeks, &c.—The cheeks and lips are most remarkable in man and those quadrupeds which resemble him, though they are found to a greater or less extent in almost all the animals that have teeth. They are formed partly of what is called the common integuments, that is, the skin and contiguous membranes, partly of the muscles formerly enumerated, and partly of a mucous membrane that lines the whole cavity of the mouth. Through the substance of the cheeks there passes on each side a pipe from the parotid glands, pouring the saliva into the mouth.

Mastication.—Only man and quadrupeds can properly be said to masticate. The toothed cetacea, reptiles, serpents, and fishes, appear to swallow their food whole, and their teeth are evidently formed rather for seizing and retaining their prey than for chewing it. Many of these latter tribes, however, particularly serpents, employ the process of insalivation, licking their prey all over before proceeding to swallow it.

Many *crustaceous* animals are furnished with jaws and other organs, either for breaking down their food or cutting off substances for which they have occasion. Thus, crabs and lobsters, besides the proper jaws, have the two large claws toothed and furnished with very strong muscles, by which they are enabled to break the shells of the testaceous mollusca on which they feed, and wasps are able to cut off pieces of flesh for their food, or particles of wood for constructing the cells in which they live, by means of their jaws. Some insects have several pairs of jaws, but in general there are only two pairs which move laterally. The larvæ, or caterpillars of insects, have also jaws with which they bite the vegetables that constitute their food.

Mastication is performed chiefly by the lateral motions of the jaws, by which the food is ground between the teeth, while it is mixed with saliva, and thus rendered more soluble in the juices of the stomach.

Rumination.—The process of rumination, which takes place in Linnæus' order *Pecora*, and a few other animals, is a sort of second mastication; the food, after being received into one of the stomachs, being partially disgorged and chewed again before passing into another cavity where it is to undergo a more perfect digestion.

In some animals, there are certain cavities where the food is laid up for a time before being finally swallowed, and where, probably, it undergoes a partial insalivation. Such are the cheeks, pouches of some apes and rats, and the *crops* of granivorous birds.

Sect. II. *Of Deglutition.*

The organs employed in deglutition are chiefly the *pharynx*, the gullet, and the tongue, of which the last has been already described.

Pharynx.—The pharynx is that opening which is seen at the back of the tongue. Its figure is nearly that of a funnel, being expanded above where it is connected with the sphenoidal bone and bone of the tongue, and growing narrower below where it terminates in the gullet. It is partly membranous and partly muscular, and the membrane that lines its inner surface is of a pretty deep red colour.

Gullet.—The gullet in man is a tube of considerable length, partly membranous, but furnished with numerous fleshy fibres. When distended it appears cylindrical, but in its usual state of collapse it is rather flat. It extends from the termination of the *pharynx* in the upper part of the neck, through the rest of the neck, and through the chest, close beside the vertebræ, but not exactly in a straight direction, till it enters the stomach. Though very small in its inactive state, it is susceptible of considerable dilatation, except at its lower extremity.

In quadrupeds.—Only the *vertebral animals* have a gullet distinct from the stomach; and its differences in the several classes are not very remarkable. Among the quadrupeds these differences consist chiefly in the greater or less muscularity of this tube, being most muscular in *herbivorous* animals, and most membranous and dilatable in the *carnivorous*. The muscular fibres run downwards in a spiral direction, crossing each other.

In cetaceous animals.—The gullet of cetaceous animals has a peculiarity of structure, consisting of a fleshy tube extending from its upper part to the internal opening of the nostrils or blowing holes, furnished with circular fibres, which, contracting during the act of swallowing, interrupt the communication which would otherwise subsist between the pharynx and the nostrils.

In birds.—The gullet of birds is sometimes of considerable size, especially in those which feed on fish. The crop of birds is merely an expanded portion from the lower part of the gullet, and forms a bag in front of this tube, and out of the natural direction of its cavity.

In reptiles, &c.—In most reptiles the gullet is larger in proportion to the stomach than in quadrupeds, and has numerous longitudinal folds which render it susceptible of considerable dilatation. In tortoises and turtles, its inner surface projects into numerous conical processes directed towards the stomach, evidently intended to prevent the return of the food. The gullet of serpents is remarkable for its great length and extreme dilatability, so that these animals can swallow a substance of greater diameter than that of their own body. The gullet of fishes is very short, but proportionally wide.

Deglutition.—The act of deglutition requires but little explanation. The food being thrown back by the tongue is received into the *pharynx*, whence, partly by its weight, and partly by the muscles attached to the pharynx, it descends to the gullet, along which it is propelled chiefly by the muscular action of this tube, assisted, in some cases, by the neighbouring muscles of the neck.

Sect. III. *Of Chylification.*

The stomach.—This organ is the only part of the intestinal canal which is found in all animals, but perhaps there is no organ which presents greater varieties. In most animals it is a single cavity; but, in many, it is either composed of several cavities, or divided into several compartments.

In man.—The stomach of man, in figure, has been compared to the bag of a bagpipe. It is largest at the extremity next the gullet, smaller at the opposite extremity, and is distinguishable into two compartments by a constricted portion nearly in the middle. The orifice by which it communicates with the gullet is called *cardia*, and is at some distance from the broad extremity. The other orifice by which it communicates with the bowels, and which is exactly at the small end, is called *pylorus*. Hence

Digestion. the two compartments of the stomach have been termed its *cardiac* and *pyloric portions*, of which the former is at least twice the size of the latter. The stomach is said to have two curvatures, a smaller extending from the root of the gullet to the *pylorus*, next the vertebral canal, and a larger on the opposite side, which, when the stomach is empty, is directed downwards, and when the stomach is distended is turned forwards. The stomach is situated in the upper part of the belly, but nearer the left than the right side, occupying great part of what from it is called the *epigastric region*. It is composed of three principal layers; a *peritoneal coat*, derived from the common lining of the belly; an internal *villous* coat, forming part of the mucous membrane that lines the whole intestinal canal; and a thin muscular coat, most evident next the pylorus, and lying between the other two. The stomach is provided with several large arteries, numerous branches of nerves, and mucous glands. It is attached to the neighbouring parts by doublings of the peritoneum, and has hanging from its large curvature a fatty membrane extending over the bowels, and called *omentum* or caul.

The division of the stomach into *cardiac* and *pyloric* portions is most evident after taking food, when the constriction is generally so great as, for a time, to prevent the food from escaping out of the *cardiac* into the *pyloric* portion.

Gastric juice.—There is a fluid formed within the stomach, different from the mucus, which naturally moistens the inside of the whole alimentary canal. It is limpid, and possesses no very sensible properties, and yet it has considerable solvent powers. This is called the *gastric juice*.

Intestines.—The remaining and longest part of the alimentary canal, called the *intestines* or bowels, is, by anatomists, divided into two primary and six subordinate portions. Taken as a whole, it is divided into *small* and *large* intestines, and each of these are subdivided into three parts. That portion of the small intestines which extends for about twelve inches from the *pylorus*, is denominated *duodenum*. It passes obliquely across the vertebræ towards the right, and is of larger diameter than the rest of the small intestines. It takes several turns, and in the posterior part of what is called its third flexure it is perforated obliquely by the biliary ducts coming from the liver and gall-bladder.

The rest of the small intestiues, which anatomists have chosen to distinguish into *jejunum* and *ileum*, occupy the greater part of the lower belly, where they make numerous turnings or convolutions. Towards the fore part and sides of the belly they float loose, but towards the back they are secured together and fastened to the vertebræ by an extensive plaited membrane called *mesentery*.

The large intestines commence in the right side of the belly, by a portion of considerable diameter, called *cœcum*, into which the small intestines open by a projecting part which acts imperfectly as a valve. The *cœcum* forms a bag of nearly a cubical form. From this bag to within about a foot of the termination of the bowels, the intestinal canal takes the name of *colon*. This portion commencing, on the right side of the belly, makes a turn upwards, and then crosses the belly immediately below the stomach, to the left side, where it makes two short turns so as to form a figure resembling the letter S, and then terminates in the rectum or straight intestine.

This last is situated chiefly in the hollow of the *sacrum* and *coccyx*, and grows larger as it descends till it terminates in the *anus* or fundament. At this exterior opening there are several muscles which act chiefly either in compressing the sides of the bowel; thus promoting its evacuation, or in contracting its outer extremity, and thus preventing the involuntary escape of its contents.

The intimate structure of the whole intestinal canal resembles that of the gullet and stomach, but the internal folds of its villous coat are more remarkable, especially in the small intestines, where they form numerous projections internally, and thus increase the interior surface of the bowels. The colon, too, in consequence of three sets of longitudinal muscular fibres, is contracted into numerous compartments or cells, which are most remarkable in the transverse arch and flexures on the left side.

Chylification.—The process of chylification appears to take place in the following manner: The food having entered the stomach, is dissolved, or reduced to a pulp, chiefly by the chemical agency of the *gastric juice*, and partly by the mechanical pressure of the stomach. This process appears to take place in the *cardiac* portion; and when it is sufficiently completed, the stricture between this and the *pyloric* portion is gradually relaxed, and the aliment, now become *chyme*, or imperfect chyle, passes into the latter portion, where it is probably mixed with a portion of bile passing upwards. Hence it is propelled by the muscular action of the pyloric portion through the *pylorus* into the *duodenum*, where it is mixed with the bile coming from the liver, and with a fluid resembling saliva, coming by another pipe from an organ called the *pancreas*, (to be hereafter described) and called the pancreatic *juice*. In this way probably is formed the perfect chyle, which is a fluid resembling milk.

The chyle, together with the superfluous or excrementitious part of the aliment, now proceeds forward through the convolutions of the small intestines, by what is called the *peristaltic* motion, which is the effect of the contracting power of their muscular coat, excited to action by the stimulus of their contents, and especially by the bile. In the progress of the aliment through the small intestines, in the healthy state of the body, the greater part of the chyle is gradually absorbed by innumerable small vessels opening internally among the folds of the villous coat, while the rest is gradually propelled into the *cœcum*. Here it probably undergoes a farther change, and hence it passes through the *colon*, where it appears to lose its remaining nutritious particles; and when it reaches the rectum it becomes mere excrementitious matter.

The comparative anatomy of the intestinal canal is of importance both to the naturalist and physiologist; and it is chiefly from it that several valuable facts respecting this function have been derived. We find that the length and complex structure of this canal depend much on the nature of the aliment employed.

In *carnivorous* animals the whole canal is in general proportionally short, and the stomach simple; whereas in those animals that live on vegetable food, the intestines are remarkably long, and the stomach is often of a very compound structure.

Stomach of quadrupeds.—The stomachs of quadrupeds, in their general structure, resemble that of man, except that their muscular coat is generally stronger and more evidently fibrous; and that in several instances, as in the hare, rabbit, horse, and ass, the division into *cardiac* and *pyloric* portions is very manifest and permanent. The stomachs of apes, bats, and lemurs, nearly resemble that of man in figure, except that of bats, which is rounder.

Ruminating animals.—It is chiefly among the ruminating quadrupeds that the stomach is formed into several separate cavities, though this compound structure is not confined to that order. Thus, the hamster-rat has two distinct cavities, the kangaroo three, and the sloth four. The structure of the stomachs of ruminating quadrupeds, as exemplified in the cow and sheep, is nearly as follows: The first stomach, or *paunch*, is the largest in the adult animal, and has its internal coat beset with numerous flattened *papillæ.* The second stomach is called *honeycomb bag*, vulgarly *king's hood*, and is considerably smaller than the former, from which it differs chiefly in the elegant cellular appearance of its internal membrane. The third cavity, called the *many-plies*, from the numerous folds of its internal coat, is the smallest of the four; and these three are connected in such a manner, that, under different circumstances, the food can pass from the gullet, either into the first stomach only, or the third only, without entering either of the others, in the first instance. The fourth stomach, commonly called the *red*, is nearly as large as the first, is shaped somewhat like a pear, and its internal coat is longitudinally wrinkled.

Camel.—In addition to this general structure, the camel tribe have numerous cells formed in the substance of their first and second stomachs, capable of being closed or opened at pleasure, and it is in these cells that the animals deposit the store of water which serves to quench their thirst when traversing the burning sands of the desert.

Cetaceous animals.—*The stomachs of cetaceous animals* is generally compound, and resembles in structure the stomachs of ruminating quadrupeds. This is the more remarkable, as these animals appear to live entirely on *fish, mollusca,* young seals, or the smaller species of their own tribes.

Both in quadrupeds and cetaceous animals the distinction between the small and large intestines is very general; but their proportional length differs very much, the large intestines being usually longest in the graminivorous quadrupeds. Many of the quadrupeds have no *cæcum.* In the cetacea, the folds of the villous coat are most remarkable, and the whole canal appears divided into cells.

Birds.—The stomachs of birds also differ in structure, according to the nature of their aliment. In those that feed on insects and smaller birds, the principal part of the stomach is a thin membranous bag; whereas in *granivorous* birds the stomach consists principally of two very thick and fleshy hemispherical portions, connected by a strong membrane, and lined with a thick horny internal coat, constituting what is generally called the *gizzard.*

The intestines of birds are proportionally longer in those that are *granivorous,* though even in them much shorter in proportion than in quadrupeds, and the distinction into small and large is very obscure. The intestines in these animals open below into a cavity, which forms a common outlet to the excrements and eggs in the female.

Reptiles, &c.—In reptiles and serpents the stomach is generally simple, though sometimes it is divided into two compartments. Its figure is extremely various, being globular in the crocodile, oval in the guana, pear-shaped in the flying dragon, and in most of the other tribes forming a long cylindrical tube but little distinguished from the gullet or intestines. The intestinal canal of these animals is generally very short, resembles that of birds, and terminates below in a similar manner.

Fishes.—In fishes the stomach is usually small, thin, and membranous, but in a few instances its sides are thick and fleshy, bearing a distant resemblance to that of birds. Their intestinal canal is also short and very uniform in its structure.

Among the mollusca, one species of *helix,* has a muscular stomach, and the *laplysiæ,* or sea-hares, have three of these, with bony processes within. Their intestines are short, but generally a little convoluted.

Crustaceous animals.—The stomach of some crustaceous animals, as the crab and lobster, consists of a membranous bag, supported by a long frame, and having at its farthest outlet those hard parts that are called teeth. There is a very short straight intestine.

Insects.—The stomach of insects is generally simple and membranous; but the intestinal canal of the locust is very complicated, and connected both with a membranous and muscular stomach.

Polypes.—Polypes may be said to be all stomach, being formed almost entirely of a membranous tube, open at one extremity, into which their prey is conveyed by numerous arms, and by which, after sufficient solution in the cavity, the undigested portion is thrown out.

There are certain organs in the neighbourhood of the stomach which appear in a greater or less degree to assist in digestion, and are therefore sometimes described among the digestive organs. These are, the *liver,* the *spleen,* and the *pancreas,* which will be considered under the organs of *Secretion.*

Chap. IV. Of Circulation and Absorption.

The circulating and absorbent systems are intimately connected. By the latter the chyle is taken up from the intestines and fluids, and decayed or noxious parts of the body are removed from situations where they might do injury, and conveyed into the general mass of fluids, the former to be distributed by the general circulating system to every part of the body, and the latter to be thrown out by peculiar channels connected with the circulating system. Hence it will be of advantage to consider them under the same chapter, though the organs of circulation must first be described before those of absorption can be properly understood.

Sect. I. *Of Circulation.*

The organs of circulation in the more perfect animals consist of the *heart*, the *arteries*, and the *veins*, and, connected with these, certain vessels called *exhalants*.

The *heart* is the centre of the circulating system. Taken as a whole, it is generally of an oval form, largest at one end, and consists of several cavities, with strong fleshy sides.

The heart of man is to be regarded as a double organ, being composed of two sets of cavities connected each with appropriate vessels; and, to understand its structure, it will be necessary to make a few observations on the nature and uses of the blood.

The vessels of the human body, as well as those of quadrupeds, cetaceous animals, and birds, contain two kinds of blood, one of a florid red, the other of a dark crimson colour. The former is that which is fitted for the nourishment of the system, is conveyed to the different parts of the body by the arteries, and is therefore distinguished by the name of *arterial* blood. The crimson blood is that which has already been distributed to the system, has lost, in some measure, its nutritious properties, and circulates through the lungs for the purpose of regaining what it had lost in its former progress through the body. This blood, which is carried back to the heart by the veins, is therefore called *venous* blood. The cavities and vessels on the right side of the heart are always found to contain the crimson or venous blood, and those on the left side the florid or arterial blood.

The human heart lies in the fore and lower part of the chest towards the left side, with its small end or *point* nearly opposite to the sixth rib, and its large extremity or *base* a little raised. It rests on one side upon that muscular membrane that forms the floor of the chest and divides it from the belly. From its relative position, the heart is divided into the right and left side.

The right *ventricle*, which forms nearly one half of the body of the heart, is a triangular cavity, extending nearly to its point, provided with thick, fleshy sides, and having its internal surface rendered irregular by numerous bundles of fleshy fibres, some of which are loose at one extremity, and are connected with tendinous parts, so fixed towards the base of the heart, that when the cavity is full, and the fleshy bundles are thrown into action, the blood is prevented from leaving the ventricle in that direction. Near the base of the heart, at the upper and back part of the right ventricle, is an orifice leading to a large vessel that conveys the blood from the ventricle to the lungs. This orifice is the mouth of the pulmonic artery, and is provided with three membranes, that are concave towards the ventricle, and convex towards the artery, and are constructed in such a manner, that when blood is passing from the ventricle into the artery, they lie close to the side of the latter; but when the artery has received its blood, they converge and form a *valve* that prevents the return of the blood into the ventricle.

Immediately connected with the right ventricle is a cavity with thinner sides, part of which hangs loose from the base of the heart towards the right and fore part; this is the right *auricle*. It is an irregular cavity, with numerous openings, especially two coming from large vessels, the one from the upper and the other from the lower parts of the body, called the superior and inferior *vena cava*, which, by their meeting, form a hollow with thinner sides than the rest of the auricle, and denominated *sinus*. The inside of this sinus is smooth, but has some remarkable folds; the inside of the rest of the auricle is rendered irregular by muscular fibres. Where the right auricle joins the right ventricle, there is an opening, about an inch wide, which admits the blood to pass from the auricle to the ventricle, but is so guarded by the apparatus already noticed as to prevent its return.

The left side of the heart is formed in a similar manner of a ventricle, auricle, and sinus, connected with the aorta and pulmonic veins. The left ventricle is longer than the right, and has thicker sides. It is joined to the right by a fleshy part common to both, and acting as a partition between them. At the upper part of its base is an opening leading to the great trunk of the aorta, guarded, like that of the right ventricle, with three membranous valves, and an opening communicating with the next cavity, capable of being closed by fleshy and tendinous fibres, as in the other side of the heart.

The left *auricle* is joined to the right by a partition, which, in the adult state, is impervious. The sinus of this auricle is larger than that of the right auricle, and has more openings communicating with it, in particular four orifices of the pulmonic veins that bring the blood from the lungs. The communication between this auricle and its corresponding ventricle differs from that between the right cavities in having its valve formed of two principal portions, instead of three, as on the other side.

The heart is inclosed in a pretty strong membranous bag, called pericardium, doublings from which pass over the great trunks of blood-vessels, and immediately and closely invest the external surface of the heart.

The arteries proceeding from the heart form two large trunks, from which many principal branches and innumerable lesser ramifications are sent off. Those of the pulmonic artery, which have received no particular names, distribute the blood through the lungs, not for the nourishment of these organs, but for a purpose already hinted at, and to be more fully explained in the following chapter.

The large artery called *aorta*, is the most important, and above a hundred of its ramifications have been distinguished by names. It will be necessary only to enumerate the larger branches and the parts to which they are principally sent.

The *aorta* rises a little upwards from the left ventricle, but soon makes a turn or arch, after which it proceeds downwards to pass through the belly. While yet in the chest, it gives off two *coronary ar-*

teries to the substance of the heart; and from the arch rise three principal branches, one on the right and two on the left. The branch on the right soon divides into two, of which one passes to the right shoulder and arm, and is named *right subclavian*, or *right brachial*, while the other, called the *right carotid*, rises up the neck to the head. The two branches on the left are the left *subclavian* and the left *carotid*. When the *subclavians* reach the arm, each is, at some point between the shoulder and the elbow, divided into two or three branches, of which the principal are, the *radial*, that passes down the fore arm beside the radius, and is felt beating at the wrist, and the *ulnar* on the opposite side.

When the *carotids* reach the top of the neck, they are subdivided into external and internal. The former supply the neck, jaws, head, and face, by eight principal ramifications; and the latter enter the skull at its base, to supply the brain and its appendages.

The *subclavians* also give off several branches to supply the lower part of the neck, the external and internal sides of the chest, and one material branch called *vertebral*, which passes upwards through the lateral holes in the vertebræ of the neck to the brain.

The *aorta* having entered the belly, gives off the the *hepatic* artery to the *liver*, the *splenic* artery to the *spleen*, the *coronary* arteries to the *stomach*, and as it passes downwards beside the spine towards the left side it gives off the *superior* and *inferior mesenteric* to the *mesentery* and the bowels, the *renal* to the kidneys, and the *lumbar* to the loins and sides of the belly.

When the trunk of the *aorta* has reached nearly the last vertebra of the loins, it divides into two common *iliac* arteries, which, like the *carotid*, are soon subdivided into external and internal; the latter supplying the contents of the *pelvis*, the former passing to the thigh and leg, and receiving, according to its situation, the names of *femoral* in the *thigh*, *popliteal* in the *ham*, and *tibial*, &c. in the leg.

Structure of the arteries.—The arteries, in their general structure, are cylindrical tubes, formed of strong membranes, interspersed with muscular fibres. Their cavities are not interrupted by membranes projecting inwards; and in the living body they have a pulsatory motion perceptible to the touch, and constituting what is called the pulse. In consequence of this innate contractile power, they propel the blood which they receive toward their extreme branches, and here they terminate in very minute tubes, called capillary vessels. They give off their branches at angles more or less acute, and several of these branches communicate together by what is called *inosculation* or *anastomosis*.

Pulsation.—The pulsation of the arteries, or the pulse, varies in frequency and strength at different ages and in different individuals. Its frequency is estimated by the number of pulsations that take place in a minute; and it is found, that in a healthy, middle-aged man, these are about seventy. In women the pulse is generally more frequent than in men, and weaker; its frequency is greatest in infancy and childhood, and least in old age, when it often falls below fifty in a minute.

Veins.—Where the *capillary* arteries terminate, the *veins* begin. These are elastic tubes; but except in the larger trunks they appear to possess no muscularity. They are distinguished from the arteries by their want of pulsation, and by having their cavities interrupted by numerous membranous valves projecting within them, and preventing the passage of the blood from trunks to branches, while they permit it to flow in the opposite direction. The veins are more numerous than the arteries, each trunk of the latter being generally accompanied by two of the former. They are also more superficial. The arteries, in general, lie close to the bones, or deep among the muscles; but besides the veins that accompany these deep-seated arteries, there are many others that appear near the surface, just below the skin, especially on the extremities and the neck, where they are evident in most people by their blue colour, and become still more visible when pressure is made on them. In this case, as the blood flows from the smaller to the larger parts of the veins, that part beyond the ligature, or farthest from the heart, becomes distended in consequence of the interrupted flow of blood.

A considerable number of the principal veins have received names which, in general, are similar to those of the arteries. The most important are the following: The *pulmonic* veins bringing the blood from the lungs; the *ascending* and *descending vena cava*, the former chiefly in the belly, or on the right side of the *aorta*, the latter in the chest; the *jugular* veins in the neck; the *basilic* and *cephalic* in the arm; the *mesenteric* upon the *mesentery*; a large vein called *vena portæ*, which performs the office of an artery in distributing blood through the liver; the *femoral* vein in the thigh; and the *saphena* in the leg.

The exhalants are small arterial branches out of the general course of the circulating system, whose office is to pour out into particular cavities, or on the surface of membranes, those watery, mucous, and other fluids, intended for lubricating the surfaces of cavities and organs. They require here no particular description.

Circulation of the blood.—The reader is now prepared to understand the general circulation of the blood. Commencing with the right auricle, it proceeds in the following course: The blood from every part of the body, except the lungs, being collected by the branches and trunks, accumulates in the right sinus and auricle of the heart, from which it is poured into the right ventricle, when the latter is not contracting. The ventricle having received its blood, contracts, and, closing the valve of communication between it and the auricle, impels the blood into the pulmonic artery, by the trunks and branches of which it is distributed through the lungs. From these organs the blood is brought by the branches and trunks of the pulmonic veins, and collected in the left sinus and auricle, whence it is poured into the left ventricle. By the contraction of this latter it is propelled into the aorta, by the trunks and branches of which it is distributed to every part of the body, passes through the capillary vessels, and is collected by the branches and trunks of the veins, brought back to the right side of the heart, and circulated as before.

Thus it appears that the blood undergoes a double circulation, first through the lungs and then through the system. The blood is impelled through the arteries chiefly by the contractile power of the heart acting from behind, and the innate muscularity of the arteries. It is carried through the veins partly in consequence of the opposition to its return afforded by the valves, and partly by the pressure of the muscles contiguous to the veins.

The description just given applies chiefly to the adult state of man. There are some peculiarities both in the structure of the heart and the circulation of the blood before birth, which will be noticed along with other peculiarities of the *fœtus* in a subsequent chapter.

The blood contained in the *veins* and *pulmonic artery* is of a dark red, and that in the *arterial* vessels of a bright red colour, but this is the only sensible difference between them. When blood is drawn either from an artery or vein, it has a uniform red appearance; but if in any considerable quantity, on being suffered to stand at rest in a vessel, it soon separates into portions of a very different texture and consistence. A great part of the blood thus changed consists of a clear fluid, generally of a pale straw colour, resembling whey, and called the *serum* of the blood. Within this floats a solid mass called the coagulum, or clot, which consists chiefly of two portions, a pretty dense gelatinous substance above, and a deep red matter, easily broken, on the lower part. The upper gelatinous part is called *coagulable lymph*, and the under part is composed of what have been denominated the red globules of the blood. By heat the *serum* coagulates.

The specific gravity of blood is rather greater than that of water; it has an unctuous feel, a saltish taste, and, when fresh drawn, a peculiar odour.

The general differences in the circulating system among the inferior animals have been already noticed in the introduction. The particular variations respect chiefly the heart.

Heart of quadrupeds.—The heart of quadrupeds and cetaceous animals nearly resembles that of man, but is not situated in the same manner. It does not lie so much to the left side, and rests chiefly on the sternum, with its base forwards. The arteries in these animals are distributed nearly as in the human species; but in some particular tribes, especially the ruminating quadrupeds, those which go to the brain have the trunk more minutely divided, so as to check the impetus of the blood in the depending posture of the head which these animals employ in feeding. A similar minute division of the arterial trunks that supply the limbs occurs in some of those animals that are remarkable for the slowness of their motions.

Birds.—The heart of birds has a peculiarity of structure in the right *ventricle*, consisting of a strong tense muscle, nearly of a triangular form, so placed as to assist in driving the blood with greater force into the lungs.

Reptiles.—The heart of reptiles varies in the different orders. In the turtles, tortoises, and the crocodile tribe, it consists of a compound ventricle, with the compartments communicating with each other, and of two independent *auricles*; while in frogs, toads, and salamanders, it consists of a single undivided conical ventricle, and a single auricle. A similar structure to this last prevails in serpents.

The circulation through the lungs in reptiles and serpents is limited and imperfect; and from the immediate communication of the ventricles, the distinction between the venous and arterial blood is scarcely manifest. From this peculiarity of structure these animals are capable of suspending respiration when below water, or in other circumstances where they are prevented from receiving continued supplies of pure atmospheric air.

Fishes, &c.—In fishes the heart is small in proportion to the body, and exceedingly simple in its structure, consisting of a single auricle and ventricle, from the latter of which arises a single artery that passes to the gills, through which the blood circulates, and is brought from them to an artery that distributes it through the body. The blood-vessels of fishes are few in number. The heart of *mollusca* in general resembles that of fishes, but that of the cuttle-fish is composed of three muscular cavities analogous to ventricles. *Crustaceous* animals have a still more simple heart, consisting of a muscular cavity that propels the blood through the system before it passes to the gills. In no other of the invertebral animals below these is there any proper circulating system.

Nutrition.—It is chiefly through the medium of the arteries and the blood that the *nutrition* of the animal system seems to be effected, though we cannot properly explain the mode in which this is brought about. We know that the blood contains within itself the component principles of the animal body, and in the course of circulation these are deposited where they are required.

This affords some explanation of those remarkable phenomena that take place in many animals with respect to the reproduction of parts that have been injured or destroyed, as in the claws of crabs and lobsters, the tail and legs, and even the eye of reptiles, and the bones and some other parts of the human body. It also explains how parts that are separated may be reunited, and how a part taken from one animal may be made to grow to a newly cut surface in the body of another.

Sect. II. *Of Absorption.*

The absorbent system is composed of two sets of vessels and glands, and a general receptacle for collecting the absorbed fluids.

Lacteals.—One set of vessels and glands serve the purpose of conveying the chyle into the circulating system. The vessels, from containing the milky chyle, are called *lacteals*; and the glands, from being situated on the mesentery, are denominated *mesenteric glands.*

Lymphatics.—The other set of absorbing apparatus consists of vessels which, from containing a clear watery fluid, are called *lymphatic*, and of lymphatic glands. It is the office of these to remove superfluous fluids, to absorb matters by the skin, or convey away particles that are noxious or useless, or that are to be exchanged for new fluids.

The lacteal and lymphatic vessels resemble minute veins, except that their coats are thinner and more transparent, and they are provided with many more valves. They open upon the internal membrane of the intestines, and traverse the mesentery through the mesenteric glands. The lymphatic vessels are partly deep-seated, arising from internal cavities, or internal organs, and partly superficial, running longitudinally below the skin, as shown in the full length figure of Plate 10. These vessels also pass through lymphatic glands; and it is remarkable, that the vessels which leave the glands on the side next the heart are fewer in number than those which enter them from the opposite extremity.

Almost every part of the body is provided with absorbent vessels, which, whether called *lacteals* or *lymphatics*, have a similar structure and appearance, resembling jointed tubes.

Glands.—The mesenteric and lymphatic glands also nearly resemble each other. They are bodies of a flattened oval form, and of a reddish brown, or greyish colour. They are composed partly of numerous minute vessels, and partly of a pulpy matter, by which these appear to be connected, and they are each enveloped in a particular membrane. They are of various sizes, from that of a millet-seed to that of a small pigeon-egg, and are usually placed in groupes of three or four together. The lymphatic glands are most evident in the neck and about the large joints, as in the groins, arm-pits, and about the knees.

Thoracic duct.—The general receptacle in which the lacteals and lymphatics terminate is called the thoracic duct; but though the greater part of it is situated within the thorax, it appears to commence in the belly at about the third vertebra of the loins. It lies partly behind and partly on the right side of the aorta, sometimes single and sometimes double, and forms two remarkable expansions, the lowest of which is called the *receptacle of the chyle.* In the thorax it unites with the left subclavian vein, into which it empties its contents, to be thence carried to the right side of the heart.

A regular absorbent system, such as we have described in man, is not found in all the inferior classes, though it is probable that absorption takes place in all of them. In the higher classes the whole absorbent apparatus resembles that of man, and the differences that take place in the rest are not sufficiently remarkable to render a particular account of them necessary.

The mode in which absorption takes place has not been completely ascertained. It is supposed that the absorbent vessels exert an active power, in the first instance, in sucking up the matters they have to absorb; and though these matters often consist of the solid parts of the body, it should seem that these must be reduced to a more or less fluid state before entering the mouths of the absorbents. The absorbed fluids appear to be carried onwards from joint to joint, by what mechanical philosophers term *capillary attraction*, and in passing through the glands they probably undergo some necessary or important change.

Chap. V. Of Respiration and Voice.

All animals, whether they live in air, earth, or water, require occasional supplies of atmospheric air to renovate their blood or juices; and they have all organs, some extremely complicated, and others very simple, by means of which they alternately receive and discharge the air, or water mixed with air, by what is called *respiration.* Most of the more perfect animals also utter sounds, or have a voice, and their vocal organs are immediately connected with the general organs of respiration.

Sect. I. *Of the Organs and Phenomena of Respiration.*

The general organs of respiration consist of the *windpipe*, the *lungs*, and *diaphragm*, assisted in their mechanical action by numerous muscles. The upper part of the windpipe also contains the organs of voice in what is called the larynx.

Without at present minutely describing the organs of voice, it will be proper to take a general view of the larynx, and windpipe, from the commencement of the former at the root of the tongue, to the termination of the latter in the lungs.

Larynx.—Immediately at the root of the tongue is situated the *hyoidal bone*, or bone of the tongue, which has received its former name from its resemblance to a Greek letter. It consists of a body and two horns, with cartilaginous appendages, with which the upper and back part of the *larynx* is intimately connected.

The external part of the larynx is composed of several cartilaginous pieces, so united as to form a short tube attached at the top of the neck, and forming there a protuberance partly angular and partly rounded, while its back part next the gullet is chiefly composed of membrane and muscles. The most conspicuous part of the *larynx* is composed of two flattish, irregular, four-sided cartilages, which, by their meeting, form that angular protuberance so remarkable at the upper and fore part of the neck, called by anatomists *Adam's apple.* These two pieces united, form what is called the *thyroid cartilage.* Between these, on the upper part, there is a moveable oval cartilage, convex next the tongue, to which it is attached, and concave towards the aperture of the larynx, over which it is turned by the motion of the tongue in the act of swallowing, so as to prevent the food and drink from passing into the windpipe. Below the thyroid cartilage there is one resembling a ring, and thence called *cricoid*, or annular. This is the hardest part of the larynx, and completes that tube below, while two other small cartilages above and behind this, called *arytenoid*, make up the rest of the larynx. All these cartilages are connected together by ligaments and muscles.

Windpipe.—The windpipe commences immediately below the cricoid cartilage, passes down the fore part of the neck into the chest, and soon after entering this cavity divides into two branches, which pass, one on each side, into the lungs. The windpipe is a tube of considerable size, formed on its fore part and sides by circular cartilaginous rings, placed one below another, while its back part is flat and membranous where it is contiguous to the gullet. Its internal surface is lined with a mucous membrane, while its outer surface is covered with a strong fibrous membrane of considerable thickness. On the upper part of the windpipe, and extending over a part of

Respiration. the thyroid cartilage, is a body called the *thyroid gland.*

Cavity of the chest.—This is a bony cavity, of a conical form, broadest next the belly and narrowest at the neck. Its front is formed by the breast-bone and the cartilages to which the ribs are attached, its back part by the twelve dorsal vertebræ, while the ribs constitute its sides. It is lined internally by a dense serous membrane, which invests all the contents of the chest, and forms two doublings in the middle, extending from the inside of the breast-bone to the vertebræ, and forming a double partition called *mediastinum.* Thus the cavity of the chest is divided into three compartments, two lateral, containing the right and left lungs, and one central, containing the heart, the large blood-vessels, the gullet, and greater part of the *thoracic duct.* The floor of the chest is formed by the *diaphragm*, which is also covered next the cavity with the *pleura.*

Lungs.—The lungs are large, membranous, cellular, spongy bags, capable of considerable expansion and contraction, and supplied with numerous blood-vessels. They take their general figure from the cavities of the chest in which they are lodged, being convex next the ribs, a little concave next the diaphragm, flattened next the mediastinum, narrow above, and broad below; their colour is generally a brownish red, brighter in childhood and youth than in advanced age; they are smooth and glossy on their outer surface, and, in the healthy state, are easily compressible, and so light as to float in water. The lungs of each side are divided into several smaller portions, or lobes.

The greater part of the lungs is composed of an infinite number of very minute membranous cells, surrounded with cellular substance; and interspersed with innumerable ramifications of blood-vessels, with nerves and lymphatics. The membranous cells have no immediate communication with the surrounding cellular substance, but they freely communicate with each other by means of short pipes, which gradually become larger and more cartilaginous as they approach the divisions of the windpipe. The blood-vessels consist partly of those which nourish the lungs, but chiefly of the ramifications of the pulmonic artery and veins which circulate the blood through the lungs. The blood thus circulated does not enter the membranous cells, but passes round them, within its proper vessels.

Diaphragm.—The diaphragm, or midriff, is that extensive partition which separates the chest from the belly. It is composed partly of fleshy and partly of tendinous fibres. At its sides it is attached to the ribs, in front to the sternum, behind to the dorsal and lumbar vertebræ, and in the middle to the *mediastinum*, in such a manner that it forms two convex surfaces towards the chest, and two corresponding concavities towards the belly. It is perforated with several holes, especially one forward and towards the right side, for the passage of the great ascending vein; a second near this, but more in the centre, of an oval form, for the gullet; and a third behind this, for the descent of the great artery, or *aorta.*

Respiration.—This function is partly mechanical and partly chemical. The air inhaled by the mouth and nostrils enters the larynx, and, by its own weight, descends through that tube and its ramifications into the air cells of the lungs. To assist this *inspiration*, the cavity of the chest is enlarged, partly by drawing up the ribs by the muscles suited to that office, and partly by the contraction of the muscular fibres of the diaphragm, by which its convexities next the cavities of the chest are flattened. When the cavity of the chest is thus enlarged, the air cells of the lungs are expanded by the rarefaction of the air which they contain, and readily admit the introduction of fresh air from without. While the lungs are thus dilated, the blood sent to them from the heart flows more freely than when they are in a contracted state.

Inspiration being completed, expiration follows. This is effected chiefly by the abdominal and neighbouring muscles drawing down the ribs, while the muscular fibres of the diaphragm are relaxed, and this partition is pushed towards the chest by the pressure of the contents of the belly. This action is assisted by the elasticity of the air-cells of the lungs, and of the cartilages of the ribs, by which the former are naturally contracted, and the latter drawn downwards.

A healthy adult man respires about twenty times in a minute, and appears to take in, during an ordinary inspiration, about forty cubic inches of air.

The chemical effects of respiration respect either the changes produced on the respired air, those produced on the blood that passes through the lungs, or those effected in the system at large.

It is found that the air respired suffers a sensible diminution in its bulk, though this is probably but trifling, amounting to about six parts in a thousand; that during respiration the air loses a part of its oxygenous constituent; that it acquires an additional quantity of carbonic acid, or fixed air; and that it is emitted by the lungs impregnated with watery vapour.

Hence it appears that, during respiration, a small quantity of atmospheric air is absorbed, that oxygen is consumed, and that carbonic acid and water are produced.

As the blood sent to the lungs by the pulmonic artery is of a dark red colour, while that brought back by the pulmonic veins is of a florid red, it is evident that a change has been effected on it by passing through the lungs. It appears that this change consists chiefly in the loss of its hydrogen and carbone, acquired in its circulation through the system, which is attracted by the oxygen of the respired air producing water and carbonic acid. The chemical theory of respiration is, however, still imperfect.

The effects produced by respiration on the system at large are partly the increase of vital energy and activity, produced by the exciting power of the arterial blood, and partly the support of animal heat.

Experience shows, that, when the breathing is free and rapid, the circulation is most vigorous and active; that breathing a pure, clear atmosphere, excites agreeable sensations in the mind, and disposes to mirth and cheerfulness, while the animal motions are rendered free and vigorous, and the digestive powers are increased; whereas, when respiration is impeded, or when a person is compelled to breathe an impure atmosphere, the circulation, especially through the lungs and head, becomes slow and languid, a peculiar anxiety is felt at the breast, which is partially relieved by yawning, sighing, or a deep inspiration; the head becomes heavy and oppressed; the face swells, and generally feels heated; the sight becomes blunted or depraved; the mind confused; and muscular action is rendered feeble and languid.

Animal heat.—Physiologists are now generally agreed, that animal heat depends chiefly on respiration. Those animals whose respiration is quickest and freest, as birds, have the greatest temperature, while those whose respiration is slowest and most languid, as reptiles, have their temperature proportionally low. The natural healthy temperature of the human body, or what is called blood heat, is about 98° of Fahrenheit's thermometer. To account for the production and continuance of animal heat, it is supposed that the venous blood, in passing through the lungs, imbibes a quantity of that heat which is extricated during the decomposition of the atmospheric air, or has its specific heat increased, and that in circulating through the body it imparts a portion of this heat to the parts to which it is distributed.

Few circumstances are more remarkable in the animal economy than the power which animals possess of preserving an equable and moderate temperature. Most of them can exist for a considerable time in air heated to a degree greatly superior to that of the blood, or cooled below the freezing point; and still, while life remains, the heat of the body is not materially increased in the former, or materially diminished in the latter case. A dog has been kept in air heated to 260°, without having his heat increased more than 2°, and men have breathed an atmosphere of 130° without being greatly incommoded. Alligators and fish have been found sporting at their ease in the waters of a hot bath; while, on the other hand, many reptiles have been enclosed in a block of ice, and still survived. These phenomena are to be attributed to the conservative effects of the vital principle; but we know that in those animals which perspire, a free and copious perspiration, the natural effect of increased heat, contributes to cool the surface of the body, and preserve its equability of temperature.

Torpidity.—The periodical torpidity, or *hybernation*, that takes place in many different animals, is intimately connected with the general phenomena of respiration. Among quadrupeds, three species of bats, at least two of bears, the badger, the hedgehog, the hamster rat, some marmots, the dormouse, and a few others, pass the greater part of winter in a state of inactivity, differing from sleep in the slowness of their circulation and respiration, and their little susceptibility of impressions from external *stimuli.* The same circumstances take place in a still more remarkable degree among tortoises, lizards, and other reptiles; and some birds and fishes, though *hybernation* is not common in these classes, are occasionally found in a state of torpor. Most insects that survive the autumn pass the winter in a torpid state; and even man has been known to remain for several days in a state of suspended animation, from the effects of cold, without finally perishing.

It is chiefly, however, in quadrupeds and reptiles that the phenomena of hybernation have been minutely examined; and the following is the result of the examination. During this state of torpidity, the animals appear scarcely to live; their sensation seems entirely suspended; their irritability is so much diminished, that they may be cut, torn, or have their legs or tail broken off, without giving any signs of motion, or expressing any mark of feeling. Their digestion, or at least their appetite for food, is also suspended, and their secretions and excretions are discontinued. The only functions which appear to be carried on, and shew that vitality is not entirely extinct, are those of circulation and respiration, which are so languid, that the animal can but just be said to breathe, and the heart to beat. In some quadrupeds too, the absorbent system still continues active; for these animals are commonly very fat when they retire to their winter quarters, but quite emaciated when they leave them in the spring. This, however, is scarcely the case with reptiles, which are found to lose very little of their weight during hybernation. In those animals which hybernate under the protection of man, it is found, that if they are removed from their retreats, and exposed to a gentle heat, they partially recover the use of their faculties, and sink again into torpidity, when remanded to their cell; but if the heat to which they are exposed be too great, or too suddenly applied, the animal is commonly destroyed.

To what immediate cause these phenomena are to be attributed, has not yet been satisfactorily ascertained. There is no doubt that they are connected with a languid state of respiration, and this seems to be one of their most constant precursors; but this alone does not afford a sufficient explanation.

The comparative anatomy of the general respiratory organs, offers many and important varieties. In most quadrupeds the lungs are similar to those of the human subject; but in those which live chiefly in the water, as the sea-horse, and in cetaceous animals, the lungs are long and flat, are not divided into lobes, and adhere to the diaphragm and to the pleura, and this last membrane is of a firmer texture than in man and most quadrupeds.

There is one peculiarity in the respiratory organs of cetaceous animals that requires particular notice. There are in the skull of these animals two bony canals proceeding from the back of the mouth, traversing the interior of the skull in a curved direction, and opening externally in some part of its upper surface. These canals constitute what are called the blowing holes, and it is through them that the animals spout those jets of water which form so remarkable an object in the Greenland seas. These canals generally unite, except in the proper whales, near the top of the head, and form externally a single opening. There are numerous membranous and bony cavities connected with these canals, and muscles for contracting and regulating their diameters.

Cetaceous animals, in their usual attitude, are incapable of breathing through the mouth, and are

Respiration. therefore provided with these openings at the top of the head, which is generally out of water; and these openings serve both as nostrils to admit the passage of air to and from the lungs, and to discharge the water taken in by the mouth along with the food.

The lungs of birds are small, flattened, adhere above to the chest, and are covered by the *pleura* only on their anterior surface. The air cells are of considerable size, and the lungs are not divided into lobes. There are also membranous air cells extending to the belly, and among them are muscular fibres which seem to supply the place of the diaphragm, an organ that is not found in birds. Besides the membranous air cells, there are large vacuities in the bones of birds, particularly in the blade bone and thigh bone, which are filled with air instead of marrow.

In reptiles the lungs are proportionally larger, and of a looser texture than in quadrupeds and birds, and the air cells are in general of considerable size. In these animals, too, there is no diaphragm. In the tadpoles of toads, frogs, and salamanders, which pass the earlier stages of their existence entirely in the water, there are also temporary gills, consisting of several fringed vascular membranes, projecting on each side of the neck, and communicating with the back of the mouth. When the animals approach their perfect state these drop off; but there are two species of reptiles, the proteus and the siren, in which they are permanent. In serpents there is properly but one lung, consisting of a very long spongy bag, a great portion of which forms a single cavity, while the other cells are very large. They also have no diaphragm.

This simplicity of structure in the lungs of reptiles and serpents is well suited to their habitation and manners of life. They are thus enabled to receive a large quantity of air at once, and to retain it for a considerable time, while the very open texture and little vascularity of their lungs make them swim and dive more readily. The respiration in these animals is naturally very slow, and can be suspended for a very considerable time.

Fishes have no lungs, but respire by means of gills, which are placed on the sides of the neck, and generally consist of four vascular plates, attached immediately to as many arched bones or cartilages, which are connected with the *hyoidal bone*. In the bony fishes there is but one external opening to the gills of each side, and this is covered with a bony or cartilaginous lid, which opens and shuts alternately as the animal respires. In the cartilaginous fishes there are several openings to the gills on each side of the neck, and no gill-covers.

Most crustaceous animals have gills situated near the attachment of the legs. Some of the mollusca, too, as the snail and slug, have similar organs, communicating with the external air through a small aperture in the side of the neck, that can be opened and shut at the pleasure of the animal. It does not appear that any of these last animals inspire air by the mouth.

Insects have air vessels passing below the skin along the body, which are largest in the caterpillar state. They communicate with the air by apertures called *stigmata*. In general these openings are placed on both sides of the body. Respiration.

The respiratory organs of worms resemble those of insects; but zoophytes, though they evidently require atmospheric air, or water that is impregnated with this air, have no perceptible breathing organs.

Sect. II. *Of the Organs and Phenomena of Voice.*

A great variety of animals are capable of producing sounds, but only the vertebral animals possess what may be called vocal organs, and of these animals a great many are entirely dumb. The most remarkable for voice are a few quadrupeds, most birds, and some reptiles and serpents.

The essential vocal organ is the *larynx*, assisted in the propagation of sounds by several of the neighbouring cavities, and assisted also in their articulation, in those animals that possess an articulate voice, by the tongue, the lips, the teeth, and the palate.

The external part of the human larynx has already been described; it remains to notice its internal parts, which are more immediately concerned in the production of vocal sounds.

This internal part of the *larynx* is called the *glottis*, and consists chiefly of several membranes, which are so situated and connected with the external cartilages, and with numerous muscles, as to produce an almost incalculable variety of tones, by regulating the quantity and velocity of the air which is made to pass through them in a given time. Two of these internal membranes have the appearance of fibrous bands, running from the side of each *arytenoid cartilage* to the internal fore-part of the *thyroid cartilage*. At this latter part they meet and diverge from each other towards the back part, but in such a manner that the space between them, constituting the principal opening or *chink of the glottis*, is capable of various degrees of contraction and dilatation, according as the *arytenoid cartilages* are made to approach each other by the action of the contiguous muscles, or recede from each other by their own elasticity. Below these are two other ligamentous membranes, having similar attachments with the former, but larger, and generally more distinct, though not moveable to the same extent. Besides these, there is on each side a membranous cavity, produced by a reflection of the membranes already described, and these are called the *ventricles of the glottis*.

The several parts of the larynx, including the glottis, have their motions varied and regulated by 23 pairs of muscles. Hence it may easily be conceived how great must be the variety of tones and inflections capable of being produced by the human voice; especially if we consider that to these must be added as assistants all the muscles that act upon the tongue, the lips, and the lower jaw, and even the principal muscles of respiration. It is computed that the number of combinations, and consequently of varieties of sound, capable of being produced by these muscles, co-operating in different manners with each other, amounts to above 17,000,000,000,000.

The general mechanism of voice and speech requires but little explanation. In the ordinary silent state of the vocal organs, the membranes and muscles of the *glottis* are in a state of relaxation; but when, Respiration. by the contraction of the muscles, and consequent approximation of the membranes, the chink of the glottis is diminished, sound, or voice, is produced, and this is more or less shrill according to the contraction of the aperture, and more or less loud according to the quantity of air forced through it in a given time. By this variation in the glottis alone, however, only inarticulate sounds, or vowels, are produced. To utter articulate sounds, we call in the aid of the tongue, the lips, the palate, the teeth, and even the nose, and the articulation is more complete according as these parts are perfect and healthy. Swelling or soreness of the tongue, dryness, or imperfections in the lips, loss of the front teeth, deficiency in the palate, or obstruction in the nostrils, each contributes to render the speech imperfect and indistinct.

Several quadrupeds have a characteristic voice, produced by peculiar organs, consisting, as in man, of four tense membranes and membranous cavities, with the addition, in some instances, of a sinus in the *hyoidal bone.*

The *neighing* of the horse seems to be produced by the vibrations of a delicate laminar membrane, attached by its middle to the thyroid cartilage, and having its extremities running along the external edges of the opening of the *glottis*. The *braying* organs of the ass consist of a similar membrane, with two large membranous bags communicating with the larynx, and a hollow in the thyroid cartilage. In the cat there are two delicate membranes situated below the ordinary membranes of the *larynx*, the vibrations of which are supposed to occasion *purring*. Two species of monkey, generally called *howling apes*, from the loud and horrible sounds they occasionally utter, appear to produce these by reverberating the air through a spherical cavity in the *hyoidal bone*. The *lowing* of cattle, and *bleating* of sheep, depend probably on the large cavities in their skull and horns.

There is a peculiarity in the larynx of cetaceous animals, which is thought to disqualify them from uttering peculiar sounds. This consists in a considerable swelling, or dilatation, below the opening of the *glottis*, while this latter is very much contracted. It is, however, asserted by those who have observed these animals in their native element, that they emit sounds resembling a dull lowing or bellowing.

In birds, the windpipe is provided with two larynxes, one at each extremity, having a peculiar opening, provided with membranes. It is also remarkable that these organs frequently differ in the male and female birds. Thus, in the male of the wild swan the windpipe makes a large convolution, which is contained in the hollow of the breast-bone, whence it is enabled to make a whistling sound, while the female, especially in the tame swan, has this organ straight, and is dumb. The windpipe of singing-birds very much resembles a flageolet, or similar wind instrument, having the reed, or mouth-piece, next the lungs, and the orifice, by which the sounds are regulated, analagous to the holes of the instrument, next the head.

It is supposed that only two species of reptiles are entirely dumb. Many of them have characteristic voices. Thus tortoises hiss or sigh; crocodiles low or roar, sometimes in a very loud tone, and the young of these animals utter piercing cries, said to resemble the mewing of a cat, when they are attacked; guanas whistle; and frogs and toads croak. Still it would appear that the vocal organs of reptiles are very simple, consisting of a single larynx, without epiglottis; but in frogs and toads, especially in the males, the membranes of the glottis are very large, and there are peculiar cavities in the sides of the head or neck connected with the glottis.

Serpents, like reptiles, have no epiglottis, and their larynx is extremely simple. Many of them are dumb, and the voice of the rest consists only in hissing.

The voice of animals alters with age; it is shriller in the young and very old, and deeper in middle-aged animals.

It is remarkable that some animals lose their voice when carried to particular countries. Thus it is said that dogs in some parts of America never bark; and that quails and pigeons in Siberia are altogether dumb.

Chap. VI. Of Secretion and Excretion.

Secretion. *Secretion* is that function in the animal economy by which certain principles are separated from the general mass of blood, by peculiar organs, for some important purposes in the system. *Excretion* differs from secretion in separating those matters which would be injurious to the system if retained, and throwing them out of the body. The secreting and excreting organs are either membranes or glands. The former, as affording covering and defence to the several parts of the body, more properly fall to be considered under the head of integumation in the following chapter; the latter will be immediately described. These consist chiefly of the *liver*, the *pancreas* or sweet-bread, the *spleen*, and the *kidneys*, with several other lesser glands, that have either been already noticed, or will be mentioned in a subsequent chapter.

The glands just enumerated lie within the belly; and as they form the only contents of that cavity not already described, it is necessary now to consider the form and composition of the belly.

The belly extends in front from the ensiform cartilage of the breast-bone to the share-bone or *pubes*; behind it is bounded by the *vertebræ* of the loins, and at the sides by the lower ribs above, and by the haunch bones below. Its sides, or walls as they are called, are composed chiefly of large and strong muscles, interspersed with fat and cellular substance, and it is lined within by a serous membrane called the *peritoneum*, which has numerous doublings that invest all the contents of the belly.

This cavity is divided by anatomists into nine parts, or regions. That part in front, extending from the pit of the stomach to within about an hands-breadth of the navel is called the *epigastric* region, as lying above the stomach, and this is bounded on the right and left by two *hypochondriac* regions, so called from being situated chiefly below the cartilages of the ribs. The middle regions are the umbilical or navel region, with the *right* and *left lumbar* at its sides; and below these lie the hypogastric in front, and the *iliac* regions to the right and left.

The *liver* is the largest gland in the human body. It is situated chiefly in the *right hypochondriac* and *epigastric*, and partly in the *left hypochondriac* regions, and is divided into two principal lobes called right and left, of which the former is the larger. It is convex towards the ribs and *diaphragm*, concave towards the stomach and bowels, a little flattened and broad at its back part, and having a sharp edge for its anterior margin. It is supported and connected to the adjacent parts, by membranous ligaments, either formed by doublings from the *peritoneum*, or covered by that membrane. Its lower surface is extremely irregular, from numerous hollows and protuberances; and here are numerous vessels and tubes connected with the liver, in particular the hepatic artery and veins, and the great vein called *vena portæ*, entering by what is called the gate of the liver, and performing the office of an artery in distributing the blood through the glandular substance of this organ. Hence the liver is extremely vascular, but its vessels are so minutely divided, and so intermixed with the proper substance of the gland, that when cut into, it exhibits a very uniform appearance, and pretty solid consistence. It is of a dusky red colour, and sinks in water.

Connected with the liver is a hollow receptacle, chiefly membranous, but partly fibrous, by some supposed to be muscular, and called the *gall-bladder*, as receiving and retaining for a time the bile secreted by the liver. This bag is of an oblong form, is attached through its whole length to the concave surface of the liver, and communicates directly with it by numerous tubes or ducts. From its smallest end or neck proceeds a pipe called the *cystic duct*, which soon unites with a similar tube called the *hepatic duct*, coming directly from the liver; and these two uniting form a common tube by which the bile is conveyed into the *duodenum*.

Bile is brought continually from the liver by the hepatic duct, and occasionally from the gall-bladder by the cystic, and the fluid from both these sources is of the same nature, except that what is collected in the gall-bladder acquires a greater consistence, and deeper colour, in consequence of the absorption of its thinner parts. Bile is a dark greenish fluid, of considerable density, viscid to the feel, of a bitter taste, and a peculiar unpleasant odour. Its specific gravity is greater than that of water. When agitated, it becomes frothy like a solution of soap, readily mixes with water, and forms with it a yellowish fluid.

The bile appears to be secreted in the glandular substance of the liver from the blood of the *vena portæ*. It undoubtedly serves important offices in the animal economy, the chief of which are probably to separate the chyle from the excrementitious part of the aliment, and by its stimulating property to propel the latter through the intestinal canal.

Only the proper worms and zoophytes appear to be entirely without a liver or analogous gland; for it is found at least in every animal that has a complete circulating system.

The liver of quadrupeds is much more minutely divided than that of man especially, in those that are *carnivorous*. In many of those animals, especially in the rat, hare, guinea-pig, and sloth tribes, in the elephant, rhinoceros, deer, and camel, in horses, seals, and walrusses, there is no *gall-bladder*, and in general this organ is confined to *carnivorous quadrupeds*.

The liver of cetaceous animals is divided much in the same way as in the human species. None of these animals have a gall-bladder.

In birds the liver is divided into two equal lobes, and the hepatic duct is distinct from the cystic. The liver is larger in domesticated than in wild birds. In general these animals have a gall-bladder; but it is wanting in some species, particularly the parrot and the pigeon, the latter of which has been proverbial for having no gall, an assertion which is not strictly true.

The liver of reptiles is always large, and in some, as the salamander, it is of very considerable magnitude. It is generally divided into two lobes, but is sometimes simple, especially in lizards. All reptiles have a gall-bladder but this is proportionally smaller than in quadrupeds and birds. A similar structure is found in serpents.

Many fishes have the *liver* of considerable size, and many of them have a *gall-bladder*. In some cases the liver surrounds the intestinal canal, and it frequently abounds with oil, even in those fish that are generally destitute of fat, as the skate and cod.

All the mollusca have a liver, which is generally very large; but it does not appear that these animals possess a gall-bladder.

In crustaceous animals there is a large organ analogous to the liver, consisting of several tubes, closed at one extremity, and opening at the other into the intestinal canal.

There are in insects several processes attached to the alimentary canal, and containing a bitter yellow fluid; and these are considered to be their biliary organs.

The *pancreas* may be considered as a large salivary gland, more immediately connected with the digestive organs than those of the mouth, as it secretes a fluid very similar to saliva, and evidently destined to assist in the process of chylification. It exists in almost all the vertebral animals, and its structure is pretty uniform in the several classes. In man it is of a long flattened form, having a small angular protuberance at the end next the duodenum. It is of a greyish colour, and internally is composed of numerous small lobes, connected together by a cellular membrane, and invested with a general external coat. Along its whole length runs a whitish tube, connected with numerous small tubes on each side, and passing in nearly a straight direction to the *duodenum*. It is situated across the belly, and behind the stomach, with its flat sides pointing forwards and backwards; and being among organs that are much exposed to motion, the progress of its secreted fluid through the general tube is thus accelerated. This fluid is commonly called the pancreatic juice.

The *comparative* differences in this organ relate chiefly to its colour, consistence, form, and composition; but these are not so important as to require particular notice here. The pancreatic ducts are sometimes more numerous than in man, and enter the duodenum by openings at a distance from the biliary ducts.

The spleen is found in all the vertebral animals, and its situation and structure are pretty uniform in all. It varies in form, size, colour, consistence, and vascularity. It is largest in man and quadrupeds, and smallest in fishes.

The spleen of the human subject is of considerable magnitude, though much less than the liver. It is placed in the left hypochondriac region, between the cardiac extremity of the stomach and the false ribs, being contiguous to the diaphragm above and to the *côlon* below. Its general figure is an oblong oval, a little compressed. It is of a soft consistence, and of a purple colour. It is sometimes cleft about the edges, and as if formed of different lobes. It is extremely vascular, being inferior in this respect only to the lungs and liver, and, like the latter, it is partly of a glandular structure, consisting of numerous cells of a whitish colour, containing a peculiar fluid.

The uses which the spleen answers in the animal economy are not yet well understood. There is an intimate connection between its vessels and those of the stomach. It has lately been conjectured, that one of its principal uses is to carry off from the stomach a part of its fluid contents to the *urinary bladder*, by a shorter passage than through the absorbent vessels.

In those quadrupeds that have a compound stomach, the spleen is situated near the *paunch;* and in the ox and sheep it is more evidently cellular than in the rest of this class.

In some cetaceous animals, as the porpoise, the spleen is composed so as to appear as if there were several. As in the ruminating quadrupeds, these are most immediately connected with the first stomach.

In birds this organ is situated just before the left lobe of the liver, within a doubling of the *peritoneum*.

Among the reptiles, the spleen of turtles and tortoises is kidney-shaped. In lizards and salamanders it is oblong, while in frogs and toads it is spherical. It is generally situated in the mesentery, pretty near the *rectum.*

The situation of the spleen in fishes is generally near the commencement of the alimentary canal. Its form in this class is extremely variable.

Before describing the kidneys, it will be proper to notice some *peculiar secretions* that take place among the inferior animals. Thus, among quadrupeds, the beaver has certain glands near the extremity of the rectum, in the form of oblong bags, which secrete that peculiar resinous matter called *castor;* and the civet-cat and musk animals have appropriate organs for secreting the odoriferous substances from which they derive their names. Several species of weasel have the property of producing a very offensive matter from the pores of the skin, when they think themselves in danger of being injured, and thus driving off their assailants.

Among cetaceous animals, the cachalots produce, in cells within the skull, and in some other parts of the body, that concrete oily substance commonly called *spermaceti;* and *ambergris* is a product of the same tribe, being generally considered as a concretion formed within the intestinal canal.

Birds have peculiar glands situated on the rump, near the root of the tail, from which is derived the oily fluid with which they trim their feathers. These organs are most remarkable in water birds, whose feathers are consequently very greasy.

Some peculiar secretions take place in reptiles, as the acrid liquor secreted from the feet of geckos, said to be of a poisonous nature, and the irritating fluid which exudes from the skin of toads and salamanders when injured. The most remarkable secretion in serpents is the venom collected in bags at the root of the upper tusks in the vipers and rattlesnakes.

In fishes there is a mucous fluid produced in tubes below the skin, and poured out by tubes or pores between the scales, for the purpose of lubricating the external surface of the body.

Many remarkable secretions take place among insects, as that viscid fluid formed by silk-worms, which afterwards hardens into the strong and beautiful matter of silk, and a similar glutinous liquor that produces the web of the spider; that acrid matter, somewhat similar to the poison of serpents, situated at the root of the sting in bees, wasps, hornets, &c.; the *lac* that constitutes the basis of sealing-wax, the acrid matter of cantharides, the colouring matter of cochineal, and several others.

Among the mollusca, the ink of the cuttle-fish forms one of the most remarkable secretions; and perhaps we may reckon among those secreted substances the silky threads by which the sea-mussel and some other testaceous mollusca attach themselves to the rocks.

The kidneys are glands fitted for separating the urine from the mass of blood. They are found in all the vertebral animals, and are pretty uniform in their situation and figure. They are always two in number, and are generally connected with a membranous receptacle, or bladder, into which the urine is conveyed by proper pipes, called *ureters*, and where it accumulates till it be discharged. Hence the kidneys may be regarded as both secreting and excreting organs.

The kidneys in man are situated in the right and left lumbar region, near the spine, and consequently in what is called the small of the back, lying in such a manner behind the bowels that the top of the right kidney is immediately below the right lobe of the liver, and the upper extremity of the left contiguous to the lower part of the *spleen*, the right being generally a little lower than the left, and their upper extremities rather longer than their lower. They are of a firmer consistence than either the liver or the spleen, and of a pale red colour. They are the only contents of the belly which are not covered by the *peritoneum*, but are involved in a considerable quantity of loose, fatty, cellular substance, from which is partly derived the proper membrane that covers the

Secretion. outer surface of the kidneys, which is of a whitish colour and fibrous texture. The kidneys are less vascular than the liver or the spleen. They are composed of two substances of different structure and consistence, one called the *cortical substance*, as it forms the outer part of the gland, of a dark colour and pretty soft consistence, the other called *medullary*, consisting of several conical divisions, terminating in what are called papillæ, which converge towards the concave depression on the inner side of the kidney, where they unite in a membranous cavity, from which rises the membranous tube called ureter.

The urine appears to be formed in the medullary part of the kidney, and collected by the membranous tubes into the cavity at the commencement of the ureter, whence it passes through these tubes, *i. e.* one to each kidney, to the bladder. The ureters pass behind the *peritoneum*, from which they receive a part of their investing membrane. They are simple membranous tubes, but not regularly cylindrical, and they are capable of considerable dilatation.

The *human bladder*, when distended, is nearly of a spherical form, a little flattened in front. It lies in the fore part of the *pelvis*, just before the *rectum*. It is partly membranous and partly muscular, and is perforated obliquely behind and near its lower part or neck, by the two *ureters*. It is attached to the neighbouring parts by membranes and ligaments, and to the *navel* by a ligamentous cord.

The general appearance of the fluid separated by the kidneys is well known. It is of rather greater specific gravity than water, and contains in solution a great variety of saline matters, and a particular substance called *urea*.

It is unnecessary to be more minute respecting this excretion in the human body. We shall therefore proceed to a comparative view of the functions in other animals.

The kidneys of quadrupeds vary chiefly in composition. In some tribes, especially the carnivorous quadrupeds, they are extremely simple; while in others they consist of numerous lobes, loosely connected by cellular substance. This structure is so remarkable in bears, that each of their kidneys resembles a bunch of grapes. All quadrupeds have a urinary bladder, which is proportionally smaller in carnivorous than in herbivorous quadrupeds; and in particular is very large in the hare and in cattle. It is more loosely connected with the neighbouring parts in quadrupeds than in man.

The kidneys of cetaceous animals are longer, flatter, and more lobular than those of quadrupeds, and the ureter proceeds from their posterior extremity. The bladder in these animals is comparatively small, and of an oblong form.

In birds, the kidneys consist of a double row of glandular bodies, situated on each side of the lumbar vertebræ. There is no urinary bladder in this class, and the *ureters* empty their contents immediately into the cloaca.

The structure of the kidneys in reptiles and serpents is extremely simple, but their form and situation vary. In tortoises they are short and thick, and are situated in the posterior part of the belly. In lizards, they are of an oblong, oval, flattened form, and lie very near the tail. Tortoises, chameleons, dragons, guanas, stellios, salamanders, toads, and frogs, have a urinary bladder, which is single in all but the three last tribes, in whom it consists of two membranous bags. Of course, in those that have no bladder, the ureters terminate as in birds.

Though all fishes possess kidneys, the majority of them are destitute of a urinary bladder.

There are several other *excreting organs* in the animal body. Thus, the skin excretes the *perspirable matter*; the lungs, *watery vapour*; and the bowels the *excrementitious part of the aliment*; but the consideration of these organs does not belong to the present chapter.

Chap. VII. Of Integumation.

Integumation. The whole surface of the body, all the internal cavities, whether muscular or bony, all the bones, muscles, blood-vessels, nerves, and, in short, almost every component part of the animal body, are invested or lined by membranes, differing from each other in their nature, texture, and extent. Many of these are secreting surfaces, and might therefore have been treated of in the preceding chapter; but as even the fluids they secrete chiefly serve the purpose of adapting them better to integumation or defence, we have thought it preferable to bring the whole under one connected view in the present chapter.

The most general investing organ of integumation is the *cellular membrane*, which serves partly as a covering and partly as a mean of separation to every organ and almost every fibre of the body. It is composed of filaments and plates, intimately interwoven, and crossing each other in every direction, forming, by their interstices, numerous spaces or cavities filled with a serous fluid or fatty matter. The fibres of which it is composed are of a whitish colour, and elastic.

The cellular membrane is one of those organs which perform more than one important office in the animal economy. Besides covering and defending the parts which it surrounds, the cells of that part of it which is most external, and which cover certain organs, as the kidneys, the heart, &c. contain and probably secrete the fat, and hence this part has been called the *adipose membrane*. This fatty matter not only serves the purpose of preserving the equable temperature of the parts which it surrounds, and preventing friction by its lubricating quality, but seems also, in many instances, especially in those quadrupeds that pass the winter in a torpid state, to supply the want of food.

There are some animals in whom this fatty matter is particularly abundant, and these are generally inhabitants of the waters. Thus all the cetaceous animals have a very thick layer of fat cellular membrane lying between the muscles and the skin, constituting what is called the *blubber*. A similar structure, but to a less extent, obtains in the aquatic quadrupeds, especially seals and walrusses, which are commonly hunted for the sake of their oil. Many fishes, too, especially the salmon and the herring, have a considerable quantity of oil within their cellular mem-

Integumation. brane, though, in general, these animals are very deficient in fat.

Another very general investing *membrane* is that called *serous*, from the watery fluid which bedews its inner surface. Membranes of this class are found in all the great cavities of the body. Within the head they constitute a delicate reticulated membrane, lying within the *dura mater*, and called the *arachnoid coat* of the brain; within the chest they form the *pleura*, and in the belly the *peritoneum*. Each of these may be said to form a distinct bag, though, in some measure, they communicate with each other through the openings between adjacent cavities. The serous membranes are of a whitish colour, of a shining appearance, having a rough, irregular surface towards the parts to which they are immediately attached, and one that is smooth and even next the cavity of which they form the lining. They are of a cellular rather than of a fibrous texture, capable of considerable though gradual dilatation, in a small degree contractile and elastic, but possessed of little sensibility.

A third membrane, scarcely less universal than the preceding, is that called *mucous*, which lines all the cavities that communicate with the external air, as the nose and contiguous sinuses, where it constitutes the *pituitary membrane*; the *larynx*, windpipe, bronchiæ, and, probably the air-cells of the lungs, the mouth, pharynx, gullet, stomach, and intestines, and all the excretory ducts, opening externally from glands or membranous receptacles. Like the former they have two surfaces, an inner, rough and irregular, and an outer, or that next the cavity, smooth and moist, but seldom regular. These surfaces, however, are composed of distinct layers, and have between them numerous small glands that secrete the mucous fluid, for which these membranes are so remarkable. The mucous membranes possess but little sensibility and contractility, though they are capable of very great dilatation.

A fourth class of investing membranes is called *fibrous*, because, more than any of the rest, they are composed of distinct fibres. Among these are the *periosteum* that covers the bones, and the *aponeuroses*, or sheaths, that envelope the muscles on the arms and thighs, the *capsular ligaments* of the joints, the *dura mater* of the brain, the sclerotic coat of the eye, &c. These are of a white glistening colour, resembling tendons, and, though sometimes connected with secreting membranes, appear to perform no secreting office in themselves.

These are the principal *internal* organs of integumation. The external are the skin, the mucous network, and the cuticle, with its numerous appendages of hair, nails, horns, hoofs, feathers, scales, shells, &c.

Skin.—The skin in the human body is composed of three distinct layers, the *corion*, the *reticular portion*, and the *papillary*, or nervous portion. The corion constitutes the substance of the skin, and is of various degrees of thickness in different parts of the body, being thickest in the palm of the hand and soles of the feet, the back, the skull, and back of the neck, while in some parts, as the lips, it is extremely thin and delicate. It is of a fibrous texture, and the fibres cross each other in every direction, and are interspersed with numerous blood vessels, nerves, and absorbents. They are of a white colour, of a gelatinous texture, and capable of considerable extension. The *corion* is every where perforated with numerous holes, constituting what are called the pores of the skin, which are arranged so as to form pretty regular angular figures of three, four, or five sides. The *corion* gives strength and firmness to the skin, and forms a connecting membrane for its nerves and vessels. In itself, it appears to have little connection with the sense of feeling.

The *reticular portion* forms the outer surface of the true skin, and appears to be produced by the ramification of numerous vessels passing through the pores of the corion, and forming a sort of net-work upon its surface. It is in this layer that the pustules of small pox and similar eruptions have their seat; hence it has been called, by Mr Cruickshank, the *membrane of the small pox*.

The *papillary*, or nervous portion of the skin, is that which covers the outer surface of the corion below the reticular portion, through the meshes of which last the papillæ project, and thus appear to form the outer layer of the skin. This portion appears to consist of the extremities of those nervous filaments that are distributed through the *corion*, and forms the immediate organ of feeling. The papillæ are arranged in bundles of small white fibres, not always of the same length, forming a sort of pencil. They are situated very close to each other, and form together a *villous* surface, well suited to receive impressions of feeling. They are found on the outer surface of the corion wherever this membrane has been examined by the microscope, but they are most remarkable at the point of the fingers, in the lips, in the palms of the hands, and soles of the feet. Hence, probably, these parts are so susceptible of tickling. The nervous papillæ are most evident when stimulated by the gentle contact of an external body, and they are generally most sensible in females and young persons.

The surface of the skin is kept moist, and the sensibility of the papillæ preserved, partly by the matter of perspiration, and partly by an oily fluid formed by very minute glands, called *miliary* or *sebaceous*, which are particularly abundant in some parts of the body, as in the arm-pits, behind the ears, &c. The matter of perspiration consists chiefly of a watery fluid, containing, in solution, a little saline matter, and commonly mixed with the fluid from the sebaceous glands. It appears to be formed by the exhalant vessels of the *corion*.

Anatomists have generally described a membrane, called the *mucous net-work, (rete mucosum,)* as being always found between the cuticle and true skin; and it is certain, that in negroes, mulattos, and probably other persons with dark skins, that such a membrane is capable of being shewn. This is usually described as a layer of mucous and glairy fluid, of a more or less dark colour; and, from its lying immediately above the reticular portion of the skin, it has often been confounded with this membrane. There seems no doubt, that the apparent colour of the skin in natives of different countries, depends much on the existence or colour of this substance. If, as we

Integumation.

suspect, it be not properly a membrane, but only a layer of mucous matter, secreted by the parts beneath, it may, in certain cases, be absorbed, and thus the dark colour of the skin may disappear. There is now living in Edinburgh, a Bengalee mulatto, about 60 years of age, who was brought to this country 50 years ago. He was then of a very dark colour; but for many years this dark hue has gradually worn away, till at present (June 1816) there remain only a few scattered dark spots, the rest of his skin resembling that of a native European.

The outermost integument of the body in all animals with which we are acquainted, is the *cuticle* or scarf skin. This is an organic insensible membrane, consisting in the human body of two evident layers, possessing little extensibility, and scarcely any elasticity. It is of very different degrees of density or thickness in different parts of the body; a circumstance which depends much on the greater or less pressure to which it is exposed. In the palms of the hands, and soles of the feet, it is extremely thick, whereas on the lips, nipples, &c. it is thin and delicate. When thick, it is composed of several layers which occasionally peel off from each other. When a part is excoriated or deprived of its cuticle, this membrane is, in general, speedily reproduced.

The outer layer of the cuticle is composed of scales lying over each other, with openings or pores between them that probably communicate with the pores of the corion. These scales are in some places so arranged as to form curved parallel lines, an appearance very evident at the points of the fingers. Its inner layer has more of a reticulated than scaly appearance, and probably has often been mistaken for the *mucous net-work*. The cuticle is naturally white, and nearly transparent. It is capable of being raised from the parts beneath by scalding fluids, or by the action of blisters; and, in these cases, the raised portion is destroyed, and a new one produced. The origin of the cuticle has not been satisfactorily ascertained. It appears to be inorganic, as no vessels can be traced communicating between it and the skin. Small filaments, indeed, have been described as passing from the skin to this membrane; but if these were of a vascular nature, it is not probable that the extensive separation of cuticle, which is sometimes the consequence of vesication, could easily take place. It is by some supposed to be an exudation from the skin, that hardens on exposure to the air; and this supposition is rendered probable by what takes place in some of the inferior animals that cast their cuticle.

The common appendages to the cuticle, in the human species, are the *hair* and *nails*; though, perhaps, the former cannot strictly be regarded as an appendage of the cuticle, as it appears to originate in the cellular membrane below the skin, and passes through the pores of the skin and cuticle, receiving an investing membrane from the latter.

Hair.—The structure of the hair is very curious. It rises from a sort of bulb within the cellular membrane, and, as it passes thence to the cuticle, each particular hair is enveloped in a small membranous transparent cylindrical tube, perfectly distinct from the hair itself. It has been supposed that the hair is invested by productions from the cuticle to its farthest extremity; but, though this supposition is carried too far, the sheaths formed from the cuticle are of considerable length. These sheaths are always of a white colour, and transparent, so that the real colour of the hair is seen through them. The hair itself, though possessed of no sensibility, has, from its growth, been regarded as a vascular body; and we know, that in a certain disease, (*Plica polonica*,) it becomes so extremely vascular as to bleed on being cut. The growth of the hair always proceeds from the roots. Except in particular constitutions, and in old age, hair that falls off during disease is generally renewed; but if it be torn up by the root it never grows again.

When a single hair is examined, it is found to possess a slight degree of extensibility and contractility, and, considering its size, it is very strong. When drawn between the fingers, its outer surface appears quite smooth, and even if drawn from root to point, but rough in the contrary direction, which is found to be owing to small conical scales lying over each other, so that their attachments are towards the root of the hair that form the cuticular coat. Hair is found to contain a considerable quantity of oil.

Nails.—That the nails are truly appendages of the cuticle appears evident, both from the circumstance that they are sometimes separated together with this membrane, and that they are similar in texture, though of a firmer consistence. They are distinguished into three parts; one forming about a sixth of the whole, constituting the root, and closely attached to the cuticle; a second forming their outer edge, distinguished from the rest by its colour being properly whiter than the rest; and a third portion, of considerable breadth, forming the body of the nail. The root of the nail is fixed between two plates of cuticle, or rather it is covered by a fold of the skin and a portion of cuticle on its convex surface, and is lined with cuticle within, while the concave surface of the middle portion lies over the skin, to which it is firmly attached by a very delicate membrane that is usually regarded as a reflection of the cuticle. If the nails are suffered to grow, they gradually turn round over the points of the fingers, and diminish the delicacy of the sense of touch.

In their intimate structure the nails are composed of several layers, the number of which is greatest next the root, so that the nail is thickest at this part. On their external surface they are longitudinally streaked.

The nails appear to possess neither vessels nor nerves, and are of themselves insensible; but the skin which they cover possesses acute sensibility, and hence any injury done to the middle portion of the nail excites considerable pain. The nails, like the hair, grow from the roots.

The comparative anatomy of the integuments respects chiefly the skin, the mucous net-work, the cuticle and its appendages.

The texture of the skin is nearly the same in all the vertebral animals as in man, differing principally in thickness and in its degree of attachment to the subjacent muscles. In general its thickness is in proportion to the size of the animal.

Among quadrupeds, therefore, the skin is thickest in the elephant, rhinoceros, walruss, horse, and ox tribes, and it is generally thicker on the back than the lower part of the body. In most of these animals it is closely attached to the muscles beneath, especially to the fleshy pannicle; but in a few instances, as the sloth, the badger, and the honey-weasel, its attachments are but few. It often happens that some of the outer cavities in quadrupeds are tinged of a beautiful colour, as the nostrils in some species of the ape, and the inside of the external ear in the fennec. This is supposed to be owing to their mucous net-work being thus coloured. Otherwise, this part, where it is found, resembles the same substance in the human body.

The cuticle of quadrupeds is of a thickness proportional to that of the skin, and in the larger animals is often marked on its surface with numerous furrows, or wrinkled into remarkable folds. In some instances, as the manes, or scaly lizards, and armadillos, it is composed of hard and firm scales, in the latter tribe resembling shell; and in several other animals which make much use of their tail in laying hold of objects, this organ is covered with a scaly cuticle.

The *hair* of quadrupeds resembles that of man in its general structure. When very coarse it takes the name of *bristles*, and when very fine it constitutes the *fur* or *wool* of an animal. All quadrupeds appear to have a covering of hair; but in a few instances, as the elephant, the rhinoceros, and the walruss, the hairs are few and thinly scattered. The strong hairs that constitute the bristles of hogs, the manes and tails of horses, and the whiskers of seals and other animals, seem to be permanent; but the softer hair is generally shed or cast once a year.

Along with the hair some quadrupeds have spines, as the hedge-hog, or quills as the porcupine, both of which partake of the nature of horn. In the former animals they are fixed, and therefore are properly appendages of the cuticle; in the latter they are so loosely attached as to fall out on violent exertion of the animal, and are commonly cast by moulting.

The nails of apes and lemurs, the claws of bats, sloths, and ant-eaters, manes, dogs, cats, and other beasts of prey, bears and badgers, opossums, kangaroos, beavers, cavies, rats and mice, marmots, squirrels, jerboas, dormice, hares, and rabbits, and the hoofs of the rhinoceros, elephant, camels, musks, deer, antelopes, goats, sheep, cattle, horses, the hippopotamus, the tapir, and hogs, all partake of the nature of the human nails, except that they are of a firmer consistence, and especially the hoofs are composed of a great number of layers. They are all attached to the last joints of the toes, and grow from the roots outwards.

The horns of quadrupeds are of two different natures. Some, as those of the rhinoceros, antelopes, goats, sheep, and cattle, resemble, in their anatomical structure and chemical properties, the nails and claws. They are generally of a conical form, with a broad basis next their attachment to the cuticle; and in many cases they are formed upon a bony mould, which constitutes their internal support, and from which they may be separated by boiling or maceration.

The second kind of horns are long, as those of deers and the giraffe, but in the former tribe they are cast and renewed every year, while in the latter they are permanent, and are real processes from the frontal bone.

In cetaceous animals the outer surface of the skin is extremely villous, and the papillæ are soft, elastic, vascular, and often of considerable length. The skin of these animals is very thick, possesses but little elasticity, and is, in general, tensely stretched over the surface of the body.

The mucous net-work in these animals is very apparent, and much thicker than in quadrupeds. As in other animals, it is of various colours, which, shining through the transparent cuticle, distinguish the colour of the animal.

The cuticle of cetaceous animals is a dense, tough, inelastic substance, composed of several layers, smooth and shining on its outer surface, but rough and resembling coarse velvet within. It is entirely without hair or scales, but is pierced with numerous large holes through which exude oil from the blubber, and mucus from the glands of the skin, to lubricate the outer surface of the cuticle.

There is nothing remarkable in the skin or cuticle of *birds;* but their appendages, viz. feathers, down-hair, beaks, and spurs, merit attention. All birds are covered with feathers, but they do not in all species extend over the whole body. Thus the neck of the vulture, and the legs of wading birds, are bare of feathers; while in the owl, and some varieties of poultry, the feet are covered to the very claws. In a few water-birds, as the penguins, the wings are covered with scales rather than with feathers.

The structure of feathers is extremely curious. At first they appear like small hairs, growing from a bulbous root, within a small, black, cylindrical tube. By degrees they assume the appearance of down, and progressively that of feathers. The feathers appear first on the wings and tail, and the quills are the last in being developed. The shaft of the quills is at first a gelatinous cylinder, with a hard, conical point, and containing blood-vessels. It is covered with a layer of black matter, which gradually splits and forms the barbs.

All *birds* change their feathers once a year by moulting, and the feathers fall off successively.

Both down and feathers are composed of a shaft and barbs, but the texture of both is finer in the former. Intermixed with these, especially in old birds, there is commonly a few scattered hairs, scarcely differing from that of quadrupeds.

The beaks, claws, and spurs of birds, are composed of a horny substance, resembling the analagous parts of quadrupeds. The spurs are supported upon a central bone, similar to that within the horns of cattle.

The structure of the skin in *reptiles* differs but little from that in the preceding classes, except that in some tribes, as frogs and toads, it adheres to the parts beneath only at a few points, so as to form

Integumation

round the animal a sort of loose bag, capable of occasional inflation. The lizards and similar tribes have generally numerous and strong subcutaneous muscles, between which and the skin there is an intimate connexion. This structure is most remarkable in the tail.

There are several diversities in the cuticle of reptiles, and especially in its appendages. In the turtles and tortoises the whole body is covered with cuticle, which is soft and delicate, except on the head, tail, and legs, where it is more or less scaly; but what is most remarkable in those animals is, the shell with which they are enveloped. This is generally a strong and hard horny substance, forming two principal divisions, one called the shield, covering the back, and another, the breast-plate, covering the whole lower part of the body. The former is more or less convex, the latter flat, and sometimes a little concave. Each is composed of numerous pieces, or plates, of which those on the shield are most deserving of attention. They are angular pieces of horn, joined together at the edges, sometimes in a smooth and even manner, and sometimes so as to overlap each other. These plates, in some species of turtle, constitute what is commonly called tortoise or turtle-shell. This whole shelly covering is invested with a thin and delicate cuticle.

Most reptiles have their toes furnished with claws, similar to those of quadrupeds; but the most remarkable appendage to the cuticle, in these tribes, is the scales with which most of them are covered. These, in some instances, as the crocodiles, consist of strong broad plates, of almost a metallic hardness, while in others, as some of the lizards, they are soft and delicate. The scales are also covered with a cuticle.

The cuticle of frogs and toads is generally smooth and slimy, but in some species it is raised into numerous tubercles or warts.

All reptiles, except turtles and tortoises, change the cuticle once a year. In most instances the cuticle is detached in separate scales, or pieces, till the whole is thrown off.

The integuments of serpents resemble those of the lizard tribes in reptiles, except that the subcutaneous muscles are more numerous. They, too, change their cuticle, but in them it is generally sloughed off whole.

The integuments of *fishes* resemble those of the smaller cetaceous animals, except that they are proportionally thinner, have in general but little fat, and the cuticle is covered with scales. It is probable that they have a distinct *mucous net-work*, to which may be attributed their variety of colours.

Some of the *mollusca* are covered with a naked skin and a smooth slimy cuticle, which is sometimes plaited into folds. The rest of these animals, constituting the *testaceous mollusca*, or shell-fish, are provided with a hard calcareous covering, sometimes in one piece, as the univalve shells, sometimes composed of two or more pieces. These shells are covered with a cuticle, and are capable of being renewed when thrown off, or repaired when injured, by a fresh secretion of calcareous matter from the body of the animal.

Crustaceous animals, as their name imports, are invested with a solid covering of more or less density and hardness, being hardest and thickest in lobsters and crabs. In general its structure resembles that of the shells of *mollusca*, but sometimes it is so thin and elastic as to resemble rather horn than shell.

The integuments of *insects* consist chiefly of a cuticle, which is generally more or less horny, and is frequently covered with hairs or scales. In their *larva*, or caterpillar state, they have a pretty dense skin, with numerous subcutaneous muscles; but this skin is repeatedly thrown off and renewed as the animal increases in size. The body of the *chrysalis* is enclosed in a uniform annular horny covering, which bursts often with considerable violence when the insect assumes its perfect state.

The skin of *worms* is thin and delicate, and, in most instances, well provided with minute subjacent muscles; the cuticle is also thin and transparent in some cases, smooth and slimy in others, covered with protuberances, or clothed with hair. The naked worms appear to cast their skin.

Reproduction.

Chap. VIII. Of Reproduction.

Having now described the several functions which are subservient to the support of animal life, and to the intercourse that takes place between an animal and the external objects by which he is surrounded, it remains only to take a view of that function by which the species is continued, to trace the gradual progress of the young animal, and to explain the circumstances by which it is distinguished from the adult.

Here anatomical description is not necessary, and indeed, in a treatise like the present, it is not intended to teach anatomy as a professional science, but to give such a comprehensive and connected view of the animal economy, as to gratify the laudable curiosity of the general reader, and admirer of nature's works. An abundant field for physiological inquiry, on the subjects of the present chapter, opens, without entering on descriptions that can be useful only to the medical practitioner, and which cannot be interesting unless they are minute.

A difference of sex prevails in all the vertebral animals; but in many of the *invertebral* classes, either the sexes are confounded, or there are no external organs.

In the human species, those glands which form the principal preparative organs of reproduction are composed chiefly of numerous ramifications of arteries and veins, forming convolutions, and connected with numerous small tubes which act as secretory ducts, and these tubes at length unite in a common canal, which, after a very tortuous winding course, enters the *pelvis*, and opens into what is called the bulb of the urethra. These organs are properly internal in the *fœtus*, and become external only a short time before birth, sometimes not till considerably after that period. Then they are enveloped each in its own membranes, though contained in a common receptacle.

Of the female reproductive organs the most material are the *uterus* and its appendages. The uterus is a triangular cavity situated in the lower part of the pelvis, between the bladder and the rectum, and retained in that situation by numerous ligaments and surrounding cellular substance. In the unimpregnated state it scarcely exceeds three inches in length, by

Reproduction.

about two at its broadest part, and its internal cavity is so small that it would with difficulty contain a large hazel nut. In shape this organ resembles a pear; its sides are thick, fleshy, and vascular, and capable of very considerable extension both in length and thickness in consequence of impregnation.

Connected with the *uterus*, on each side, lies an oval body called *ovary*, as containing the *ova*, or rudiments of the fœtus, and between each of the ovaries and the uterus there is a tube of communication, by which the *ova* from the former are conveyed into the latter.

When an *ovum* is thus detached from the *ovary*, and received into the *uterus*, it is soon attached to one side, gradually becomes enveloped with peculiar membranes, and surrounded by a fluid. The gradual developement of the *fœtus* during pregnancy is extremely curious. About four weeks after conception the embryo is not larger than a common fly, of a soft mucilaginous consistence, without extremities, but having the rudiments of intestines covered by a transparent membrane, a moving point that is to form the future heart, and an evident head, with two black dots in the place of eyes. It appears suspended by the belly, and attached to the *uterus* by a slender cord. In a fortnight more its size increases to that of a small bee, its consistence grows firmer, and the rudiments of the extremities begin to make their appearance. At the end of three months its shape is tolerably distinct, and it is about three inches long. At four months, it is about five inches long, and its motions begin to affect the mother. By six months it has acquired the length of nine inches; and in one month more it is in general capable, if expelled from the *uterus*, of being kept alive and nourished.

A *foetus* of eight months has the following peculiarities. Its bones are soft and cartilaginous; their protuberances form distinct portions, and, in particular, the bones of the head, are soft, yielding, and not all united to each other, especially the frontal and parietal bones, between which there long remains an unossified space, called the opening of the head. The head itself, and consequently the brain, is much larger in proportion to the rest of the body than at any future period. The muscles are soft, white, and flaccid, the spinal marrow and nerves proportionally large, the nose broad and flat, the external auditory passage imperfect and cartilaginous, the eye large and protuberant, the mouth small and without teeth.

The heart, and large blood-vessels in immediate connexion with it, present several important differences in the *fœtus*. There is an oval hole in the partition between the right and left auricles, provided with a valve so situated as to permit part of the blood from the right auricle to flow into the left, while it prevents any from flowing in a contrary direction. There is also between the right and left arteries a large canal forming a complete communication between them, so that most of the blood from the right ventricle flows directly into the aorta, and a very small quantity is transmitted to the lungs.

Hence the lungs of the *fœtus* are smaller, firmer, and of a darker colour than those of a child after birth. Indeed they much resemble the liver in consistence, and like it sink in water. In the upper and fore part of the chest, between the folds of the mediastinum, there is found in the *fœtus* a large glandular body called the *thymus gland*, the use of which is not certainly known, though it is supposed to be connected with the nutrition of the fœtus.

The *liver* in the fœtus is very large, and its two principal lobes are nearly of equal size. From it there pass blood-vessels through the navel of the *fœtus*, to and from that vascular mass called the *placenta*, by which it is connected with the *uterus*. The vessels are enveloped by integuments, and form what is called the *umbilical* cord or navel string.

From what has now been said, it appears that the circulation of the *fœtus* before birth differs in several respects from that of the child after birth. It proceeds as follows. The *fœtus* is in the first place supplied with blood from the mother through the medium of the placenta, from which it is conveyed through the umbilical vein to the liver. Hence one part of the blood, without entering the liver, is carried off by a branch of the umbilical vein, and through a neighbouring branch of one of the hepatic veins, into the great ascending *vena cava*, while the rest of the blood circulates through the liver by the ramifications of the venæ portæ, and is thence also carried into the ascending vena cava. The blood from the placenta and the blood from the liver are conveyed into the right auricle, whence part of it is sent through the oval hole into the left auricle, while the rest passes into the right ventricle, by the contraction of which it is propelled into the root of the pulmonic artery; but on account of the large communication between this and the aorta, most of it passes immediately into this latter vessel, while a small portion is sent to nourish the lungs, whence it is brought to the left auricle of the heart, from which it passes into the left ventricle, and is propelled into the *aorta*. Now, while part of the blood is sent through the system by the ramifications of the aorta, another part is carried aside by the *internal iliac arteries* through the two umbilical arteries, and along the umbilical cord to the *placenta*, whence it is brought back and circulated as before.

The natural food of an infant for some months after birth is the milk secreted in the breasts of its mother. These glands are situated between the integuments and the pectoral muscles, to which latter they are attached chiefly by cellular substance and fat, and the breasts contain a quantity of fatty matter in their composition. The proper glandular part consists of several lobes that are extremely vascular, and are well supplied with nerves and absorbents. The principal secreting part is composed of a great number of small tubes, called lactiferous ducts, which appear to originate in the extremities of the arteries, gradually uniting into trunks, and passing in a radiated manner from each lobe to the base of the nipple. Here they are usually coiled up in a spiral form, though capable of being distended when the nipple is drawn out. They form from twelve to eighteen orifices opening on the surface of the nipple.

The milk of the human female differs from that of the cow chiefly in three circumstances; in having a greater quantity of oily matter, which cannot easily be separated from the curd; in containing much less

Reproduction.

curdy matter in its serous part; and in containing a greater quantity of saccharine matter.

Without adverting to the usual sexual distinctions, here we may notice the general differences that distinguish the male and female of the human species. These differences have been remarked in almost every part of the organization. Thus the whole female skeleton is said to be generally smaller than that of a male of the same age; the head, hands, and feet, proportionally smaller; the neck longer; the lower extremities shorter; the *pelvis* more capacious; and the prominences of the bones less remarkable. The muscles are also in general smaller and more flaccid; the ball of the eye proportionally smaller, its coats and membranes thinner; the skin of the eye-lids of a lighter colour and less wrinkled; the arch of the eye-brows less prominent; the eye-brows themselves finer and thinner; the aperture between the eye-lids when the upper lid is raised smaller and narrower, and the corners of the eye more acute. The larynx is smaller in women than in men in the proportion of nearly one-half, and the angular projection of the *thyroid cartilage* is much flatter in the former. The integuments in general, are thinner, softer, and less hairy.

The preparatory glands of quadrupeds in their intimate structure resemble those of man; but in many tribes and species they are rather internal than external, being concealed within the belly.

The *uterus* of female quadrupeds differs considerably in form and composition. In apes and lemurs it is a single cavity of a pyramidal or oval form. In bats, in the dog tribe, the seal, the hedgehog, the mare, and cow, the principal cavity is also single, but there are connected with it two tubular openings or horns, which in some tribes are convoluted towards their remote extremities. A third class of quadrupeds has the uterus partly double, or provided with capacious horns, as the hare tribe; and a fourth, as the opossums and kangaroos, have it double through its whole extent. The sides of the uterus in quadrupeds are much thinner, and more membranous, than in the human species.

Some quadrupeds, as kangaroos, and some of the opossums, have a sort of supplemental uterus, into which the young are received immediately after birth, and where they are sheltered and nourished till they are capable of sustaining the injuries of the weather. This is called the *abdominal pouch*, and consists of a cavity formed by a fold in the integuments of the belly, and provided with an external opening, capable of being more or less contracted by appropriate muscles, and enclosing the dug and teats.

The dugs or *mammæ* of quadrupeds differ from the breasts of women in most tribes. In apes and bats indeed they are situated on the breast, but in most other quadrupeds in the posterior part of the belly, or the teats are arranged along the belly in two rows. It is generally supposed that the females of quadrupeds have twice as many teats as the number of young which they usually produce, a rule to which, however, there are several exceptions. The teats of quadrupeds differ from the nipple of the human breast in having a single large tubular opening for the passage of the milk.

The time of *utero-gestation*, or the period of pregnancy in female quadrupeds, is extremely various, though in general proportional to their size. Thus the squirrel, rat, ferret, and probably the guinea-pig, go with young about six weeks; the fox about the same period; the hare and rabbit about a month; the cat eight weeks; the bitch and otter nine weeks; the wolf rather more than three months; the sow four months; the ewe and hind five months; the rein-deer eight months; the cow and arctic walrus nine months; the mare eleven months; the camel twelve months; and the elephant twenty-one months.

The usual number of young produced at a birth, by various species of quadrupeds, as far as it has been distinctly ascertained, is as follows. The sloth, rhinoceros, elephant, walrus, camel, hind, cow, and mare, usually produce one; the ape, seal, porcupine, rein-deer, she-goat, usually two; bats from two to five; the bitch, fox, wolf, lioness, tigress, cat, otter, Virginian opossum, mole, squirrel, hare, produce four, five, or six; the jackal, ferret, guinea-pig, mouse, rabbit, from eight to ten, or sometimes twelve; and the rat and sow from ten to eighteen or twenty.

The reproductive organs of cetaceous animals nearly resemble those of ruminating quadrupeds; but, from the peculiar form of these animals, the situation of these organs is a little different. The milk of the female is said to resemble that of the cow, but to be rather richer. Their period of gestation is not exactly known, but it is supposed that the female goes with young about ten months. They generally produce only one at a birth, which they suckle for about a year.

This function in birds offers several peculiarities both in organization and phenomena. The seminal glands lie within the belly, near the kidneys, and their excretory ducts terminate near the rectum in a dilated part. In both sexes the external organs are situated within that cavity we have already described as common to these organs and the extremity of the intestines, and called *cloaca*. There is in birds a single ovary, situated near the liver, and generally consisting of numerous, round, yellow bodies, contained each within its own membrane, and forming the future yolks of the eggs. With the ovary is connected a membranous, expanded tube, from which arises another membranous tube, long and convoluted, called the oviduct. This is susceptible of considerable dilatation, and terminates in an expanded portion, connected with the cloaca by a short tube, contracted in the usual state of the animal, but easily dilatable. The rudiment of the egg is first extricated from the membrane that contains it in the ovary, and is received by the first expanded portion, where it is completed as a yolk. Hence it passes into the oviduct, where it remains till it has acquired its white and shell, after which it is gradually propelled into the cloaca.

The period of incubation, or the time during which a hen-bird sits on her eggs, varies in the different species. Thus the humming-bird sits twelve days; the canary-bird, black-bird, wren, and pigeon, a fortnight; the hen three weeks; the duck, goose, turkey, and eagle, about a month; and the swan and ostrich about six weeks.

The *general structure of a bird's egg* is familiar to

Reproduction.

every one; but it may be proper to mention the names by which physiologists have distinguished its several parts. The skin lining the shell is called the membrane of the *albumen*, or white of the egg. Within this are two whites, of which the inner surrounds the yolk, enveloped in a peculiar delicate membrane, called the *yolk-bag*. From the two opposite sides of this bag there extend two white, knotty bodies, called *chalazæ*, terminating in the white of the egg by a flocculent extremity. On the surface of the yolk-bag, there is a small, white, round spot, commonly called traddle, surrounded by one or more whitish concentric circles, called *halones*. The use of these latter parts is not known.

The progress of the chick during incubation has been minutely examined in the common domestic fowl, and is as follows. At the end of the first day, there is perceived, near the traddle, a small shining spot, of an oblong form, with rounded extremities, and narrowest in the middle. On the second day this has acquired a curved form, and resembles a gelatinous filament, closely surrounded by a peculiar membrane, and there is a slight appearance of red vessels on the surface of the yolk-bag. On the third day the heart is observed to pulsate. It resembles a convoluted canal, consisting of three dilated portions, lying close together in the figure of a triangle, and forming the rudiments of an auricle, a ventricle, and an artery. About the same time the vertebral column of the chick is observable, of a crooked form, and the rudiments of the eyes appear. By the fourth day the chicken is nearly half an inch long, and the stomach, bowels, and liver, are discernible, and a vascular membrane forms about the navel, from which it extends within the membrane of the *albumen*, covering nearly the whole inner surface of the shell. The lungs are also apparent, but respiration is not yet properly begun. By the sixth day the chick is about seven lines long, and begins to shew signs of motion. On the ninth day ossification commences, and several bony points appear, especially round the edge of the sclerotic coat of the eye, which then resembles a circular row of pearls. By this time elegant yellow vessels begin to appear on the surface of the yolk-bag. On the fourteenth day the rudiments of the feathers are visible about the wings, and the chick opens its mouth for air, if taken from the shell. On the nineteenth day it is capable of uttering sounds; and on the twenty-first it quits its prison.

In *reptiles*, the seminal glands are also internal organs, and are situated, as in birds, near the kidneys. In the males of some of these animals, there are hard, brown, or blackish tubercles attached to the thumb and palm of the fore feet, which are most visible during the pairing season. This structure is found in frogs and toads. The female organs resemble those of birds, except that in some species, as turtles and tortoises, there are two ovaries. In the female of one species of toad, the pipa, or Surinam toad, there are numerous hollow cells in the back of the animal, in which the ova are placed by the male after being fecundated, and where they remain shut up, by the skin contracting round them, till they are capable of maintaining a separate existence.

All reptiles, like birds, are *oviparous*, though in the salamander the eggs remain in the oviduct till hatched. The eggs of turtles, tortoises, and the several varieties of lizards, nearly resemble those of birds, but are of a rounder form, and are often covered with a membrane resembling parchment, instead of a calcareous shell. The eggs of frogs and toads are gelatinous, and connected together like a twisted string of beads.

The progress of the young animal in some of the reptile tribes is not less curious than that of the *fœtus* or the chicken, especially in the frog and toad tribes, the young of which is called a tadpole, and undergoes several remarkable changes. When first extruded, there is only a small dark speck in the centre of the gelatinous *ovum*, which in two days is a little enlarged, but still retains a spherical form. In four days, this central spot resembles a small kidney-bean, and in one day more has assumed the shape of a half crescent. On the sixth day it has increased in length and thickness, and become straighter, and the distinction of head and tail, with the rudiments of eyes and mouth, is visible. By the seventh day this distinction is more evident, and there are visible the rudiments of feet and gills. The tadpole has now increased considerably, and quits the egg. About the ninth day the head and body are enlarged, and the tail increased in length. From this time to the twentieth day, the gills are very evident, but by the latter period are withdrawn below the skin. Hitherto the tadpole has had only the hinder legs, but by the twenty-fourth day the fore-legs begin to make their appearance. The body of the little animal is still transparent, and the bowels are distinctly seen through the integuments. The tail also still continues, but in a few days gradually disappears. In about two months all the legs are developed, and the animal becomes a perfect frog.

No reptile, if perhaps we may except the salamander, hatches her eggs, but buries them in the sand or earth, or drops them in the waters, to be hatched by the genial heat of the sun.

The organs and phenomena of reproduction in the *serpent tribes*, so nearly resemble those of most reptiles as not to require a separate examination.

The principal male organs of *fishes* constitute what in the bony fishes is called the *soft roe*, consisting of two long flat bodies, of a white colour, and an irregular outer surface, but soft and pulpy within, having an excretory duct passing through the middle of each, and terminating at the back part of the *rectum*. These bodies are situated beside the intestines, and the left lobe surrounds the rectum. In the cartilaginous fishes these glands more resemble those of the warm-blooded animals in their granular texture, though still of a soft consistence.

The hard roe of female fishes is also different in the bony and cartilaginous fishes; in the former it consists of two long bodies, resembling in form the soft roe of the male, but of a much firmer consistence, and fitted with a prodigious number of globular eggs. These eggs are so numerous, that, in a carp not more than eighteen inches long, there have been counted 350,000. The two parts of the roe are enveloped in distinct membranes, till they approach the *anus*, where they unite by a common tube. In the carti-

Reproduction.

laginous fishes, the female roes resemble the ovaries of birds and reptiles, and the *ova* are like yolks, of no inconsiderable size. There is also in these fishes a double oviduct, uniting as it terminates in a *cloaca*.

It is well known that fishes at certain seasons shed the *ova*, or *spawn* as it is called, from their roes, and leave it to be hatched in the waters.

The seminal glands of *mollusca* generally resemble the soft roe of bony fishes, but contain a number of small tubes, which are expelled by the animal in an entire state. In snails and slugs these tubes resemble little darts, which the animals, for these species are hermaphrodites, shoot at each other.

Most mollusca, however, are male and female, and the female contain the ovaries. The eggs extruded from these ovaries are in some species, as the cuttle-fish, united together, so as to resemble a bunch of grapes.

Crustaceous animals have generally a distinction of sex. Thus, in crabs, the male is distinguished from the female by the smallness and narrowness of his tail, which, in the latter, is long and broad, and provided with numerous fimbriated appendages for retaining the spawn. In the female crab there are two transparent membranes below the middle of the tail, communicating with the parts within. In many of the *insect tribes* there are three genders, males, females, and neuters. In the first the seminal glands are often remarkable for their size and the convolutions of their vessels; and the ovaries of the female insects sometimes increase to such a degree before the eggs are extruded, as to render the animal's belly many times larger than its ordinary size.

Most insects undergo two changes before coming to the perfect state. When the egg is hatched, it produces a caterpillar or maggot, which is called the *larva* of the insect, generally having numerous legs, and jaws capable of cutting and tearing. This *larva* gradually increases, occasionally changing its skin, till it has attained its full size in that state. It then gives over eating, generally spins a web around it, or contracts its body, and becomes covered with a horny coat; it is now a *chrysalis*, or nymph, and remains in a state of apparent torpidity till the season arrives for its assuming the perfect state, when it bursts its shell and appears a winged insect.

Several of the *worms*, as leeches, earth-worms, and a few others, are hermaphrodites, and mutually impregnate each other. With respect to others, especially the intestinal worms, there is a difference of opinion; some authors considering them as male and female, while others seem to regard them as hermaphrodites.

Some *zoophytes*, as sea-urchins and star-fish, have evidently ovaries, which, at certain seasons, form a very conspicuous part of their structure; but in general the animals of this class have no generative organs, and reproduction in them takes place by sprouts or buds that form on the body of the parent animal, and, on being detached, are gradually developed into the form and dimensions of their parent.

Chap. IX. Of Death.

Of Death.

The functions considered in the preceding chapter gradually decay as old age advances, and at length cease altogether. This cessation of the functions, independently of accident or disease, constitutes natural death,—an occurrence which, in the present state of society, is by no means common.

The approach of natural death is slow and gradual. The external functions cease one after another; all the senses are successively lost, or the ordinary causes of sensation pass over them without making their usual impressions. The eye becomes obscure and dim, and its humours at length no longer transmit the images of objects to the retina. Sounds strike upon the ear confusedly, and this organ soon becomes entirely insensible to them. The integuments grow hard and horny, and, many of their vessels being gradually obliterated, exercise the sense of touch in an obscure and indistinct manner. All the organs dependant on the skin become weak and decay; the hair and beard grow white, and, deprived of the juices which should nourish them, the hairs of the head gradually fall off. Odours are no longer perceived by the nose, or they are perceived but faintly. Tasting usually survives the rest of the external senses; but that, too, at length becomes imperfect or depraved.

The functions of the brain partake of the imbecility of the external senses; the memory no longer retains those occurrences which are every day taking place, though it long recals those of past times with relish and delight; the imagination becomes dull and often depraved, the judgment weak and wavering.

As the animal functions intimately depend on the nervous system for their vigour and activity, it is to be expected that the former must be enfeebled as the latter decays. Locomotion becomes difficult and painful; the body totters at every step; the voice grows weak; the tongue faulters, and articulation is indistinct. Circulation and respiration diminish in frequency and vigour; the appetite is in general less keen and less frequently excited; digestion languishes; many of the secretions no longer take place; the circulation in the minute vessels, from the diminished energy of the heart and larger arteries, gradually ceases; the heart at length is unable to propel the blood from its ventricles; the circulation through the lungs being thus arrested, these organs cease to inspire, make their last expiration, and terminate the life of the animal.

Thus, in natural death, the brain may be said to die first, and the heart and lungs last; but in violent or accidental death, life may cease in either of these latter organs, before it ceases in the brain. The action of this last may be completely impeded, and circulation and respiration may continue for a considerable time; but, in general, when the action of the heart is suddenly obstructed, as by a wound, or the lungs overwhelmed, as in cases of suffocation, the death of the brain soon follows.

The usual signs of approaching death are, a quick, small, indistinct and intermitting pulse, coldness and clamminess about the extremities, dimness and hollowness of the eyes, collapsed features, an unusual prominence of the bones of the face, a hollowness at the temples, and a sharpness of the nose. The ordinary signs of death having actually taken place, are, the want of respiration, as commonly shewn by the brightness of a mirror held before the mouth remaining undiminished; rigidity of the limbs; complete loss of motion; the collapse, opacity, and insensibility of the eye; the want of pulsation in the heart and arteries; the coldness of the body; the paleness or lividity of the countenance, the relaxation of the lower jaw, the regurgitation of liquids to the mouth; the insensibility of the membrane of the nostrils; the collapse, paleness, and wrinkling of the lips; and, lastly, putrefaction. Of all these, however, the last is the most certain and indubitable.

Few circumstances can be conceived more humiliating to the pride of man than the changes produced on his frame by death. Let us, for example, contemplate a female in the prime of youth and the bloom of health and beauty. Those elegantly rounded and finely formed limbs, that graceful flexibility of movement, that gentle warmth, those cheeks crimsoned with the roses of delight, those eyes brilliant with the spark of love or the fire of genius, that countenance enlivened by the sallies of wit, or animated by the glow of passion, altogether seem united to form a most enchanting being. A very short time suffices to destroy the illusion. Often, without any apparent cause, motion and sensation cease, the body loses its heat, the muscles collapse and disclose the angular prominences of the bones, the eyes lose their lustre, the cheeks and lips acquire a livid hue. These are but preludes to changes still more disgusting. The flesh becomes successively blue, green, black, and attracts humidity; and while one portion evaporates in infectious effluvia, another dissolves into a putrid sanies, which, ere long, is also dissipated. In a word, after but a short lapse of time, there remain only a few earthy or saline principles. The other component elements of the body have mingled with the air of the atmosphere, and are destined to enter into new combinations.

On the *particular* cause of death, it is not the business of this treatise to enter, and the general *immediate* cause is involved in much obscurity. It has generally been attributed to the increased rigidity of the animal fibre; but this alone is insufficient to account for the change produced. In our investigations concerning the cause of death, as with respect to the causes of many other natural phenomena, we reason in the dark; and, in fact, we can better describe what death is, than point out its immediate or proximate cause.

Chap. X. History of Anatomy and Physiology.

The early history of anatomy and physiology is of course but little known. That mankind had, at a very remote period, some acquaintance with the structure and functions of the human body, and of those animals that were killed in the chace, or offered as sacrifices to the Deity, is reasonably to be inferred from the natural curiosity and observant faculty of man. The field of battle might occasionally exhibit parts of the human skeleton, and extensive wounds might sometimes afford an opportunity of examining the structure and position of some important internal organs.

Among the Egyptians.—As a science, physiology is supposed to have been first cultivated in Egypt, where the pillars of Hermes were inscribed with all the medical knowledge of that people. These inscriptions so completely regulated the practice of medicines that if a practitioner deviated from their rules in the slightest points, and his patient died, he was considered guilty of murder, and subjected to punishment. It has been supposed that the practice of embalming, which was employed among the Egyptians from time immemorial, affords a proof that this people were skilful anatomists. But this operation, as far as it required anatomical skill, was very simple, consisting chiefly in abstracting the brain and contents of the chest and belly, and filling these cavities with resins and spices.

The Greeks.—Scientific anatomy and physiology were early cultivated among the Greeks, as we learn from the writings of Homer, which contain several passages that shew him to have been acquainted with the animal structure.

Democritus, the philosopher of Abdera, contemporary with the great physician Hippocrates, appears to have been one of the earliest dissectors of dead bodies. He is said to have examined several of the inferior animals with a view to discover the nature and seat of the bile, on the morbid state of which he conjectured madness to depend.

Hippocrates, among his numerous writings, has left several chapters on anatomy. He enumerates the bones, and describes their forms, processes, and connexions; he mentions several of the ligaments, particularizes some of the muscles and nerves; he describes the structure and pulsation of the heart, and even speaks of a circle of the blood. He supposed that a native fire resided in the left ventricle of the heart, and that the use of respiration was to cool and moderate this fire, and thereby preserve the equable temperature of the system. This native fire also acted as a vital principle, and regulated all the functions both of mind and body, through the intermediate agency of certain faculties or powers.

The writings of Plato and Aristotle contain the rudiments of the physiology of their times. Plato supposed the heart to be the source of courage and passion, and the liver of desire; the head to be the seat of reason, the chest of strength and anger; and he agreed with Hippocrates in his notion of the use of the lungs as coolers of the body. Aristotle attributed to the soul these faculties which he denominated nutritive, sensitive, and rational; the first being the principle of life, the second the origin of feeling, the third the source of the understanding. This philosopher cultivated comparative anatomy, and in his history of animals frequently adverts to their internal structure. In his general physiology he agrees with Hippocrates.

In the school of philosophy established at Alexandria, Herophilus and Erasistratus were celebrated for their knowledge of the animal economy. They were assiduous dissectors, and, if we may credit the historians of that age, were allowed to dissect alive the bodies of condemned criminals. Herophilus paid great attention to the nervous system, and was well acquainted with the structure of the brain. He is said to have been the first anatomist who employed a human skeleton for teaching osteology. Erasistratus first discovered the valves of the heart, and he suggested the idea that the bile was secreted by the liver. He also seems to have traced the chyle, in its passage through the intestines.

The early anatomists supposed that the arteries contained only air; and it was not till the beginning of the second century of the Christian æra that Rufus Ephesius proved that they contained blood. He supposed, however, that the blood entered the arteries only after death.

Galen, who flourished in the middle of the second century, established a system of physiology, which prevailed in the schools of medicine and philosophy for many ages. He proved that the arteries naturally contain blood; and he was the first to demonstrate that the larynx was the organ of voice; he adopted the principle of Plato, and introduced the notion of temperaments. Of these he supposed there were four, which he denominated, from the humour that prevailed in each, *sanguineous*, *phlegmatic*, *bilious*, and *melancholic*.

Among the moderns.—Modern anatomy and physiology may be said to have originated in the beginning of the fourteenth century with Mundinus, a physician of Milan, who published a regular system of anatomy, which superseded the treatise of Galen; but it was not till after the invention of printing had facilitated the circulation of books, that these sciences began to make any considerable progress.

In the sixteenth century there arose many eminent anatomists, who materially advanced the progress of the science by their original and important discoveries. We may particularise Berengarius of Carpi, professor of Bononia, Charles Stephanus, Fernelius, Andernach, and more especially Vesalius. This last eminent anatomist demonstrated that the blood could not pass immediately through the partition between the ventricles of the heart, as had been suggested by some preceding writers. It was now suspected that there was a communication between the arteries and the veins, though how the blood flowed from the former into the latter was not ascertained. Columbus, the disciple of Vesalius, produced additional proof that the blood flowed from the arteries into the veins in the lungs; and Cæsalpinus, who lived towards the latter end of the sixteenth century, proved that the blood passed from the extremities of the arteries into the extremities of the veins, and that in these latter vessels it *sometimes* flowed from the branches into the trunks. Still, however, he entertained the idea that the blood flowed backwards and forwards from arteries into veins, and from veins into arteries. About the same time, Fabricius of Aquapendente, professor at Padua, discovered the valves of the veins, which had however been observed, though not distinctly marked, by some preceding anatomist. Fabricius had the merit of tracing them fully, and calling the attention of his disciples to their nature and uses.

Circulation of the blood discovered.—One of the disciples of Fabricius was our countryman Harvey, who ardently prosecuted the investigation of the valves in the veins, till he discovered their true use to be impeding the passage of the blood towards the arteries. Thus he shewed, that having entered the veins, the blood must proceed through them towards the heart; and as it was known that the blood flowed in the arteries from trunks to branches, he naturally concluded that there must be a perfect circulation from one side of the heart to the other. Harvey, therefore, is now generally allowed to have been the real discoverer of the circulation of the blood, a discovery which he published to the world in 1628. This important discovery was followed by as important a revolution in the theory of medicine, which will afterwards be noticed.

Absorbent vessels.—The discovery of the circulation of the blood was soon followed by another scarcely less important, that of the absorbent system. The *lacteals* were first observed by Asellius of Pavia, in 1622, in consequence of his opening a living dog. He traced them as far as the mesenteric glands, and gave them the name of lacteals, from the milky colour of the chyle. He thought, however, that they terminated in the liver. Soon after Pecquet, a French anatomist, discovered that the chyle passed to the heart, and observed the thoracic duct. Olaus Rudbeck and Thomas Bartholine, the former a Swedish, and the latter a Danish anatomist, some time after the discoveries just noticed, observed the *lymphatic* vessels, and found that they terminated in the thoracic duct. In 1654, Glisson proved that these lymphatics are absorbents; and in 1664 and 1665 their valvular structure was discovered by Swammerdam and Ruysch.

Van Helmont, &c.—During all this time physiology had been making slow advances. From the time of Arnold of Villa Nova, and Paracelsus, it had been founded almost entirely on chemical or astrological principles, till Van Helmont introduced an intelligent being, called *archæus*, seated in the epigastric region, and having under him several subaltern ministers, situated particularly in the head, chest, and belly, by whom he executed all the animal functions.

The *archæus* of Van Helmont was superseded by the animal spirits of Willis and Descartes; and thenceforward the nervous system, and especially the *pineal gland*, the supposed seat of the soul, became an important object of attention.

Boerhaave, &c.—The metaphysical system of Descartes continued with some modifications till the end of the seventeenth century, when the mechanical philosophers, with Pitcairn and Boerhaave at their head, effected a new revolution. Borelli had some time before shewn how the muscular motions of the animal body might be explained on the principles of mechanics; and his disciple, Bellini, had extended the application of these principles to other functions. The animal body was now likened to a machine, the solid parts of which act according to their figure, bulk, and proportion, and according to the general laws of motion, while the direction, qualities, and effect of the circulating fluid, were subjected to the laws of hydrostatics. In short, every thing in the animal machine was reduced to an assemblage of cords, levers, pulleys, conduits, and canals.

Mechanical physiology was soon, however, modified by Hoffman and Stahl, the former of whom saw the necessity of a mutual action between the solids and the fluids; while the latter, convinced of the insufficiency of mechanical principles alone to explain the phenomena of vitality, strongly and successfully recalled the attention of physiologists to the effects of the *vital principle*, and introduced the theory of a self-preserving action, or what he called the healing power of nature. According to him, every thing in the animal body depends on the union of its organic parts with the active self-preserving principle which governs, according to special laws, those phenomena which may be more particularly termed vital, and which are most independent of the will.

Haller.—Haller improved on the theory of Stahl; and pursuing the route that had been marked out for philosophical inquiries by the immortal Bacon, set himself to collect and arrange the physiological facts that had been already observed. Haller saw the inconvenience of strictly applying the laws of mechanical philosophy to the actions of the living system, and explained the animal motions on the principle of irritability, a power which he considered peculiar to the animal body. To Haller we are indebted for many curious researches respecting the formation of bone, the mechanism of respiration, the action of the nervous system, the structure of the heart, the circulation of the blood, the pulsation of the arteries, and the developement of the *fœtus*. He also cultivated comparative anatomy, which he regarded as of the greatest importance in the improvement of physiology.

Cullen.—The physiology of Cullen is founded chiefly on that of Hoffman, and consists in referring the actions of the animal economy to the movement of the vital solids, as regulated by the fundamental laws of the nervous system. The vital solids, by which are meant the muscular fibres, the blood-vessels and nerves, were all supposed to originate from the last, and to be concentrated in the brain; and all the physical actions of a living being were supposed to depend on the contractility inherent in the moving fibres, excited either by their own extension, by the application of external *stimuli*, or by the immediate action of the nervous fluid.

Hunter.—Cotemporary with Cullen were the two Hunters and the second Monro, all eminent both as anatomists and physiologists. Dr William Hunter improved the anatomy of the absorbent system and that of the gravid uterus. Mr John Hunter added considerably to our knowledge respecting the structure and formation of the teeth, and the nature and properties of the blood, which he supposed to be the immediate seat of vitality. Monro improved both the anatomy and physiology of the nervous and absorbent systems; made several discoveries in the structure of the eye and ear; considerably advanced the study of comparative anatomy, and was among the first to draw the attention of physiologists to the effects of electricity or galvanism on the animal economy.

Brown.—John Brown, at first the disciple and afterwards the rival of Cullen, for some time attracted considerable notice in consequence of a modification of Haller's doctrine of irritability, which he called excitability, and which he considered as the ruling agent that directed all the operations of the animal economy. By the action of stimuli, or exciting powers, the excitability is exhausted. By the abstraction of stimuli, or by rest and sleep, it is accumulated; and on the proper adjustment of the exciting powers, so as to preserve an equable and moderate excitement, depends the healthy state of the animal system. It would be out of place here to detail the doctrines of these medical physiologists, as they must hereafter come under our review in the history of Medicine. It will be sufficient, therefore, to remark, that the theory of Darwin, lately so fashionable in the medical world, is little more than a modification of that of Brown; and that the sensorial power of the former is synonymous with the excitability of the latter.

During the latter half of the eighteenth century, the anatomy of the human body received considerable improvement from the writings of Winslow; Albinus, especially on the bones and muscles; Douglas, chiefly on the muscles; Zinn, on the eye; Sabatier; Soëmmering, on several parts of anatomy, especially the brain, eye, and ear; and Scarpa, chiefly on the nerves, the ear, and the nose.

Of late considerable attention has been paid to Comparative Anatomy. This had been cultivated by Eustachius, Vesalius, Harvey, De Graaf, Blasius, Swammerdam, and Tyson, among the earlier modern anatomists; and in the latter end of the 18th century, by Vicq d'Azyr, Daubenton, Townson, Bonnet, the Hunters, the second Monro, Camper, and Blumenbach. In the present century it has received many important additions and improvements from Cuvier, Dumeril, Lamarck, Lacepede, Macartney, Carlisle, and Sir Everard Home.

Chemistry connected with physiology.—Chemistry holds some share in the physiology of the present day. From the rhapsodies of Paracelsus and his followers, chemical physiology had fallen into disrepute, till it was in some measure revived by Boyle, Mayow, and Hales, in the latter end of the 17th century. The two latter, in particular, pointed out the relation of chemistry to physiology in the function of respiration, and shewed that the pure part of the atmosphere, now called oxygenous gas, and denominated by Mayow the nitro-aerial particles of the atmosphere, performs an important office in the animal economy. Chemical physiology was farther improved by Black, Crawford, Cavendish, Irvine, and Priestley, and still more lately by Lavoisier and the chemists of the French school. Within these few years, however, it was carried to an extreme little less absurd than the doctrines of Paracelsus, by some German chemists, particularly Hufeland, Girtanner, and Humboldt, who, transferring the operations of the laboratory to the animal body, have supposed life to depend on the combinations of oxygen with the vital principle, and on the reciprocal balance of the chemical affinities of all the elements of the animal body. At present, the application of chemistry to physiology is confined chiefly to the functions of digestion and respiration.

Galvanism.—There is one other department of

History.

natural science, connected partly with mechanical philosophy and partly with chemistry, that has for some time influenced the physiological doctrines of the present day,—we mean animal electricity or Galvanism. The effects of ordinary electricity on the animal body, especially in the concentrated form of lightning, had been long ago observed by Dr Franklin; and Professor Galvani of Bologna having observed convulsive motions to take place in the limbs of a frog, in consequence of its nerve being touched with an instrument in connection with an electrical machine, pursued the inquiry, and discovered that modification of electricity which received its name from him. The effects of Galvanism on the animal system were successively investigated by Valli, Fowler, Robison, Volta, Wells, Humboldt, Aldini, and Ritter.

System of Bichat.—Among the latest systems of physiology, deserving particular notice, is that of Bichat, who divides life into organic and animal, the former being common to all organized beings, plants as well as animals, while the latter is confined to animals alone. Each kind of life comprehends two orders of functions which succeed each other in an inverse series. Thus, in animal life, the first order of functions commences with external objects, and proceeds towards the brain, comprehending motion, voice, external sensation, internal sensation; while the second order begins in the brain with internal sensation, and proceeds externally to voice and motion. In the first order of functions the animal is passive; in the second he is active: through the medium of the first, external objects act upon the body, while, by means of the second, the body reacts on external objects. The functions belonging to organic life are those of digestion, respiration, circulation, absorption, secretion, and reproduction. The brain is the centre of animal life,—the heart, of organic life.

According to Bichat, the proper balance of life is preserved by the due proportion between the action of surrounding bodies, and the reaction of the system. As the reaction is greatest in youth, the vital principle is then predominant, and this principle is defective in old age, as the reaction is then the least. The measure of life, then, is the difference existing between the efforts of external agents to destroy life, and the internal resistance to support it. The excess of the former indicates the weakness of life, that of the latter shews its strength.

Explanation of Plates.

Plate 6.—Fig. 1. A front view of the Skeleton. A, the frontal bone; B, the parietal bone; C, the temporal bone; D, the upper maxillary or jaw-bone; E, the lower jaw-bone; F, the vertebræ of the neck; G, G, the clavicles; H, H, the scapulæ, or shoulder-blades; I, I, the humerus; K, the radius, and L, the ulna, the two bones of the fore-arm; M, the bones of the carpus, or wrist; N, the bones of the hand, or metacarpus; O, the bones of the fingers; P, the sternum, or breast-bone; Q, Q, the ribs; R, the vertebræ of the loins; S, the sacrum; T, T, T, T, the bones of the pelvis; U, U, the femur, or thigh-bone; V, V, the patella, or knee-pan; W, W, the tibia, or large bone of the leg; X, X, the fibula, or small bone of the leg; Y, Y, the os calcis, or heel-bone; Z, Z, the metatarsal and tarsal bones of the toes.

Plates explained.

Fig. 2. Side view of the Human Skull. A, the frontal bone; B, the parietal bone; C, the temporal bone; D, the upper jaw-bone; E, the lower jaw-bone.

Fig. 3. The skull of the Monkey. A, the frontal bone; B, the parietal bone; C, the temporal bone; D, the upper jaw-bone; E, the lower jaw-bone.

Fig. 4. The skull of the Elephant; the most remarkable parts of which are the projections of the jaw-bones. A, is the upper jaw-bone from the projecting part of which, at B, proceed the tusks C; D, is the lower jaw-bone, and the projecting part is at E.

Fig. 5. Is the skull of a species of Hog, the *sus babyroussa*. A, is the frontal bone; B, the upper jaw, from which arise the remarkable tusks D, which are curved backwards and downwards; C, the lower jaw.

Plate 7.—Fig. 1. exhibits a general view of the muscles: 1, is the *triceps extensor cubiti*; 2, the deltoid muscle; 3, the *teres major;* 4, *latissimus dorsi;* 5, pectoral muscle; 6, *obliquus descendens abdominis*; 7, *rectus abdominis*; 8, 8, *sartorius*; 9, 9, *rectus femoris;* 10, 10, *vastus externus;* 11, 11, *vastus internus;* 12, *gastrocnemius;* 13, *solæus;* 14, *tibialis anticus.*

Fig. 2. is a view of the bones of the right hand. The palm of the hand is here represented: *a*, is the radius; *b*, the ulna; *c*, the scaphoid bone of the carpus or wrist; *d*, the lunar bone; *e*, the cuneiform bone, *f*, the pisiform bone; *g*, trapezium; *h*, trapezoides; *i*, capitatum; *k*, unciform bone; *l*, the four metacarpal bones of the fingers; *m*, the first phalanx; *n*, the second phalanx; *o*, the third phalanx; *p*, the metacarpal bone of the thumb; *q*, the first joint; *r*, the second joint.

Fig. 3. is a representation of the palm of the left hand, when the integuments are removed, and the muscles and ligaments of the fingers are brought into view: *a*, tendon of the *flexor carpi radialis; b*, tendon of the *flexor carpi ulnaris; c*, tendons of the *flexor sublimis perforatus, profundus perforans*, and lumbricales; *d*, *abductor pollicis*; *e, e, flexor pollicis longus; f, flexor pollicis brevis; g, palmaris brevis; h*, *abductor* of the little finger; *i*, annular ligament of the carpus; *k, k*, tendons of *flexor digitorum sublimis*, which are perforated by *l, l*, the *flexor digitorum profundus*; *m*, lumbricales; *n*, *adductor* of the thumb.

Fig. 4. is a view of the inferior surface of the bones of the left foot: *a*, the great knob of the heel-bone; *b*, a prominence on its outside; *c*, the hollow for tendons, nerves, and blood-vessels; *d*, the anterior extremity of the heel-bone; *e*, part of the astragalus; *f*, its head covered with cartilage; *g*, the internal prominence of the navicular bone; *h*, the cuboid bone; *i*, the internal cuneiform bone; *k*, the middle, and *l*, the external cuneiform bone; *m*, the metatarsal bones of the lesser toes; *n*, the first, o, the second, and *p*, the third phalanx of the lesser toes; *q*, the metatarsal bone of the great toe; *r*, the first, and *s*, the second joint.

Fig. 5. a view of the upper part of the left foot, shewing the tendons of the muscles of the toes: *a*, the

cut extremity of the tendo Achillis; *b*, upper part of the astragalus; *c*, heel-bone; *d*, tendon of the *tibialis anticus*; *e*, tendon of the *extensor pollicis longus*; *f*, tendon of the *peronæus brevis*; *g*, tendon of the *flexor digitorum longus*; *h*, *h*, the whole of the *flexor digitorum brevis*.

Plate 8.—Fig. 1. exhibits a view of the viscera of the thorax and abdomen.

A, B, the right and left lungs; C, the heart; D, the right auricle; E, the *vena cava descendens*; F, F, the subclavian veins; G, G, the internal jugular veins; H, the descending aorta; I, the pulmonary artery; K, the anterior edge of the diaphragm; L, L, the two great lobes of the liver; M, the round ligament; N, the gall-bladder; O, the stomach; P, the spleen; Q, Q, some of the large intestines; R, R, the jejunum and ilium.

Fig. 2. which represents the stomachs of the *lama*; *b*, the gullet; *c*, *c*, the paunch; *d*, the cells that appear in two places of this stomach; *f*, the second stomach, or hood; *e*, the canal leading from the gullet to the third stomach, *g*, *g*, *g*, *g*; *h*, *h*, the fourth stomach; *i*, a tubercle opposite to the orifice of the *pylorus*; *k*, *l*, the juncture of the third and fourth stomachs.

Fig. 3. exhibits a section of the brain. λμλ, the *callous body*, or central portion of the brain; *MM*, the third ventricle; *mm*, fourth ventricle; φ, canal of communication between the third and fourth ventricles; *E*, pineal gland; 16, mammillary portion of the brain; 47, 48, situation of the organ of amativeness, according to Spurzheim; 57, 58, 59, transparent partition of the brain; 61, anterior commissure of the brain; 62, centre of the fundamental part of the *cerebellum*; 86, 87, 88, 90, fibres in the middle line of the nervous apparatus; II, the organ of philoprogenitiveness, according to Spurzheim; III, organ of inhabitiveness; X, organ of self love; XIII, organ of benevolence; XIV, organ of veneration; XVIII, organ of firmness, or determinateness; XIX, organ of individuality; XX, organ of form; XXIX, organ of language; XXX, organ of comparison.

Fig. 4. represents the anterior part of the right external ear, the cavity of the tympanum, the small bones, cochlea, and semicircular canals: *a*, the malleus; *b*, the incus, with its long leg resting on the stapes; *c*, membrane of the tympanum; *d*, *e*, the Eustachian tube, covered by *f*, *f*, part of the circumflex muscle of the palate; 1, 2, 3, the three semicircular canals; 4, the vestibule; 5, the cochlea; 6, the *portio mollis*, or soft portion of the seventh pair of nerves; A, the malleus; B, the incus; C, the stapes, which is connected to the latter by the intervention of D, the orbicular bone. The bones of the ear are represented in the lower figure, in which they are separated, by the same letters.

Fig. 5. is a representation of the right eye and its appendages, part of the bones of the orbit being cut away. A, the eyeball; B, the lacrymal gland; C, the abductor of the eye; D, attollens; E, levator palpebrae superioris; F, depressor oculi; G, adductor; H, obliquus superior, with its pulley; I, its insertion into the sclerotic coat; K, part of the obliquus inferior; L, the anterior part of the frontal bone cut away; M, the *crista galli* of the ethmoid bone; N, the posterior part of the sphenoid bone; P, the carotid artery; Q, the carotid artery within the cranium; R, the ophthalmic artery; aa, the optic nerve; b, the third pair; c, its joining with a branch of the fifth pair; d, the ciliary nerves, from the lenticular ganglion; the remaining letters of this figure denote the nerves going to the different parts of the face.

Plate 9.—exhibits a general view of the blood vessels: A, the heart, from the left ventricle of which proceeds B, the ascending aorta; C, the arch of the aorta, from which arise D, D, the carotid arteries; E, E, the subclavian arteries; F, F, the subclavian veins coming from the superior extremities and uniting with G, the vena cava superior; H, the jugular vein, which also joins the vena cava superior; I, the temporal artery; K, the humeral artery which divides into L, the ulnar artery, and M, the radial artery; the two latter arteries in their minuter divisions communicate with each other, and are distributed to the palm of the hand and the fingers: N, the descending aorta, which in its course gives off arteries to O, O, the kidnies, and the other viscera, and divides at P into the two iliac arteries; these latter, when they pass out of the cavity of the body and proceed along the thigh, assume the name of the femoral or crural arteries; Q, the bladder; R, the vena cava inferior, formed of the two iliac veins, by which the blood is brought from the lower extremities and conveyed to the right side of the heart, from which it is sent by the pulmonary veins to the lungs; the ramifications of the arteries and veins in the lungs are seen at S, S.

Plate 10.—Fig. 1. exhibits a view of the lymphatics, in an entire subject, which was prepared by the perseverance and industry of Mr Fyfe, demonstrator of anatomy in the University of Edinburgh; and to his liberality we are indebted for permission to copy the figure for the illustration of this part of our work.

A, section of the upper extremity of the sternum, and of the inner extremity of the clavicles, which are turned up; B, B, the internal jugular veins; C, cavity of the right side of the thorax; D, D, the pericardium cut; E, the heart; F, F, the convex surface of the diaphragm; G, G, the integuments and abdominal muscles turned up; H, part of the liver; I, the stomach, and part of the colons hrivelled; K, K, the descending aorta; L, right common iliac artery; M, M, inferior vena cava; N, N, mesentery and small intestines turned to the left side; O, cavity of the pelvis; F, the pubes; S, S, S, inguinal glands distended with quicksilver; T, T, T, branches of the vena saphena major.

The course of the absorbents is so obvious in the figure that letters of reference become unnecessary. They are seen on the upper part of the feet deriving their origin from the toes, and trunks arising from the soles of the feet appear behind the inner ancles. The lymphatics from the outside of the feet and ancles run across the tibia to the inside of the leg; and the principal lymphatics of the leg lie near the great vena saphena, and proceed to the inner side of the knee, and from thence to the inner side of the thigh. In the course of the lymphatics upwards, they form an irregular plexus on the inside of the limbs in gene-

Plates explained.

ral. The inguinal glands at the upper extremity of the thigh receive the lymphatics from the inside of the thigh. These glands are distinctly seen on the right side of the figure, and the vessels appear shooting from them in a radiated form; and on the same side is seen the iliac plexus, formed by the trunks which ascend, partly from the inguinal glands behind Poupart's ligament, and partly from the contents of the pelvis, along with the iliac blood-vessels. The lymphatics which originate on the surface of the *os sacrum* are visible at the bifurcation of the aorta. Some appear at the sides of the inferior cava, and over the aorta. The vessels and glands forming the lumbar plexus are also seen, and a few of many injected lacteals on the mesentery directing their course toward the thoracic duct.

Trunks of absorbents descend from the lower part of the liver, and from the other viscera, and meeting with the lacteals and lumbar plexus, terminate in the thoracic duct. A large lymphatic gland which seems to be formed of convoluted branches appears on the convex surface of the diaphragm, and large lymphatic vessels which perforate the diaphragm from the right side of the liver enter this gland.

On the superior extremities an extensive plexus is formed by the superficial lymphatics which pass from the anterior side of the extremity upward, and receive many branches which ascend in an oblique direction from the opposite side of the arm. The lymphatics of the superior extremities enter the axillary glands, and the principal trunks proceed from these glands, and terminate in the trunk of the left arm along with the thoracic duct. On the right side of the neck are seen some of the lymphatic vessels and glands which form the jugular plexus; and the general termination of the lymphatics of the right side of the head and neck, right arm, &c. is in the angle formed by the right internal jugular and subclavian veins.

Fig. 2. exhibits an outline view of the different layers of the skin of a negro who died of small-pox; *a*, is the cuticle; *b*, a layer of a finer texture; *c*, the *rete mucosum*, which in the negro is black; *d*, the membrane of small-pox and other cutaneous eruptions, according to Mr Cruikshank; *e*, the cutis, or true skin.

Fig. 3. is a representation of the arrangement of the pores of the skin, as they appear in the corners of certain angular parts of the surface.

Fig. 4. is a view of the gall bladder, its ducts and connection with the intestines: *a*, the gall bladder; *b*, the cystic duct; *c*, the hepatic duct; *d*, the *ductus communis choledochus*, or common duct; *e*, *e*, the pancreatic duct; *f*, the entrance of the common duct into the duodenum.

Fig. 5. exhibits a view of the jejunum, a part of the small intestines of a person who died soon after taking food, when the lacteals distributed on the mesentery were distended with chyle; *a*, *b*, *c*, the intestine; *d*, *d*, the minute branches of the blood-vessels; *e*, *e*, the trunks of the blood-vessels; *f*, *f*, the lacteals; *g*, *g*, *g*, the mesenteric glands.

ANALCIME, a variety of the mineral substance called Zeolite has received this name from its deficient electric property. See MINERALOGY.

Anaxagoras

ANAXAGORAS, an eminent philosopher of ancient Greece, who flourished about 500 years before the Christian era. He is represented as a man of rank and wealth in his native country, Ionia; but with an eager thirst after knowledge, he relinquished the whole to his friends, and engaging in the pursuits of philosophy, "devoted himself wholly," as Cicero expresses it, "to the divine pleasures of learning and the investigation of truth." He repaired to Athens; became a disciple of the Ionian school established by Thales, and spent 30 years of his life in that celebrated city, either as a scholar or a teacher of philosophy. Pericles, famous for his military skill and martial prowess, and Euripides, the tragic poet, were numbered among his pupils. But the opinions of Anaxagoras were too refined for the crude notions which prevailed in the period when he lived. He was charged with innovation in the doctrines of religion, and condemned to death. By the influence of Pericles, this sentence was commuted into banishment. The sayings of the philosopher on these transactions are recorded to have been the following: On the first, he observed, "Nature, long ago, pronounced the same sentence against me;" and when a friend expressed regret on account of his exile, he replied, with a consciousness of his own importance, which some may not unreasonably be disposed to charge to self-conceit, "It is not I who have lost the Athenians, but the Athenians who have lost me." He died at Lampsacus, to which place he retired after his expulsion from Athens; and, in commemoration of the sublime knowledge which he taught, an altar was erected, on which the words *Truth* and *Mind* were inscribed.

The traditionary history of the philosophical doctrines of Anaxagoras is vague and contradictory. But if it be true, as Cicero has asserted, that he first taught, that "the arrangement and order of all things were contrived and accomplished by the understanding and power of an infinite mind," no mean opinion can be held of the extent of his intellectual powers, the grandeur of his views, and the accuracy of his reasonings and conclusions.

ANAXIMANDER, a Greek philosopher, who flourished 600 years before Christ, was the disciple and successor of Thales in the Ionic school, and is said to have been the first of the Grecian philosophers who taught in public, and delivered the principles of his doctrines in writing. As a proof of the progress of this philosopher in mathematical and astronomical learning, the discovery of the obliquity of the ecliptic, the invention of the sun-dial, and the construction of an artificial globe, on which were delineated the divisions of land and water, are ascribed to him. He supposed that the stars are composed of air and fire, which are carried round in their spheres by portions of a divine animating power; that the sun, which is 28 times larger than the earth, occupies the highest place in the heavens; the moon holds the next, and the planets and fixed stars the lowest, while the earth is stationed in the common centre or middle of the universe. To *infinity*, concerning the precise meaning of which inquiry would be useless or unsatisfactory, Anaximander attributed the first principles of all things, or the origin of the universe. "All things are produced by *infinity*, and all things terminate in it," was the general expression of his doctrine. The followers of this philosopher were denominated Anaximandrians.

ANAXIMENES, a Greek philosopher, flourished about 556 years before Christ, and was the disciple and successor of Anaximander in the celebrated Ionic school. Anaximenes ascribed the first principle of all things to air, or a subtile æther, which is infinite, immense, in perpetual motion, and animated by a divine principle. From this air or æther, which seems to be analogous to the *moisture* of Thales, and the *infinity* of Anaximander, proceed fire, water, and earth, by the process of rarefaction and condensation. The earth he supposed to be a body with a flat surface, resting on the air, and the sun, moon, and stars to be igneous masses.

ANBERTKEND, a word which, in some of the oriental languages, has the expressive signification of "the cistern which holds the water of life," is applied to a celebrated Brahminical book containing an exposition of the Hindoo religion and philosophy. This work consists of fifty discourses, each of which is divided into ten chapters; and a translation from the original into the Arabic is designated "the marrow of intelligence."

ANCESTORS, derived from a Latin word which signifies "to go before," denote those from whom a person is descended in a direct line. The peculiar marks of respect and honour, often approaching to a kind of worship, bestowed on ancestors, forms a striking feature in the character of different nations, both ancient and modern. The veneration in which the departed spirits of their ancestors were held by the Romans, and the ceremonious duties performed to their images, which were distinguished by the name of *lares*, *lemures*, or, *household gods*, are familiar to the classical reader. Impressed with similar sentiments, the Russians honour the memory of their ancestors by the celebration of anniversary festivals, under the appropriate name of *kinsman's sabbaths*, when they make solemn visits to the tombs of the dead, with offerings of provisions. Some of the African tribes, believing that the spirits of their fathers exercise a guardian care over their concerns, undertake no affairs of importance without a previous sacrifice of rice and wine to conciliate their favour; the groves, which are supposed to be the residence of these invisible protectors, are regarded as peculiarly sacred, and no woman or child is permitted to approach them. The Moors on the northern shores of Africa shew great respect to their deceased friends. Their tombs are kept clean and whitewashed; and to small temples which are erected over the tombs they resort on holidays, to offer up solemn supplications. But the veneration paid to ancestors by the Chinese is still of a more marked character. Private acts of adoration, accompanied with offerings of perfumes and spiceries, are performed at stated times, and solemn festivals, which are held in spring and autumn, are instituted by public authority in honour of their ancestors. But the striking peculiarity in these ceremonious observances among the Chinese, is the ingenious fiction of elevating their deceased relatives to the same rank with their descendants, when the latter are fortunate in attaining a higher station in society than the former enjoyed, and according to this rank the kind of worship to which they are considered as entitled is regulated.

ANCHISES, a Trojan prince, and the father of Æneas, who is celebrated by Virgil as the great progenitor of the Roman people. According to fabulous history, Venus, captivated with the personal charms of Anchises, appeared to him under the assumed character of a nymph, and bore him Æneas, in whose perilous adventures she acted a conspicuous part. At the destruction of Troy the aged Anchises was carried from the scene of desolation on the shoulders of his son, and died in Sicily.

ANCHOR, a strong, heavy, and crooked instrument, which is attached to a vessel by a rope or cable, and is dropped to the bottom of the water in which a vessel floats, for the purpose of retaining it in any station that is required. For the construction of anchors, see SHIP-BUILDING.

ANCHOR, *to cast*, is the act of letting go the anchor when a vessel is brought to the requisite station; *riding at anchor*, is when a vessel is secured or retained in a proper station; *weighing anchor*, is the act of heaving up the anchor from the bottom when a vessel changes its station, an operation which is performed by means of the windlass in small vessels, and by the power of the capstan, wrought by numerous hands, in large ships; and *sweeping an anchor* is performed by dragging a rope, the ends of which are fastened to two boats, and the middle is sunk with a weight, along the bottom where the anchor which has been detached from the cable is supposed to lie, and in this way to discover and secure it.

ANCHORAGE, the duty which is levied on vessels for the privilege of coming to anchoring ground, and is analogous to *shore dues* paid by vessels frequenting a port or haven.

ANCHORET, a hermit, or solitary monk. See Anachoret.

ANCHOVY, a species of clupea, which is very abundant in many parts of the Mediterranean, and is the source of an active and lucrative fishery. See Ichthyology.

ANCHUSA, Alkanet, or Bugloss, a genus of plants belonging to the Pentandria class. The root of the *anchusa tinctoria* communicates a fine red colour to oily matters, and is, on account of this property, employed in pharmacy as an ingredient in plasters and ointments. This species is a native of the Levant.

ANCIENT DEMESNE, a tenure by which all manors belonging to the crown, in the time of William the Conqueror and St Edward, were held. Their numbers and names were entered in *Doomesday-Book*. The tenants in *ancient demesne* are of two kinds, one of which holds their lands by charter, and the other by copy of court-roll, at the will of the lord, according to the custom of the manor. Tenants holding originally by this tenure were bound to perform certain services for the maintenance of the king's household; and they were entitled to peculiar privileges.

ANCISTRUM, a genus of plants belonging to the Diandria class.

ANCLAM, an ancient sea-port town in the duchy of Pomerania, and in the circle of Upper Saxony, in Germany, is secured on one side by lofty walls and deep moats, and on the other by a considerable extent of marshy ground, interspersed with rich meadows, which have been long celebrated for excellent pastures; is the capital of a small territory; has manufactures of soap and silk stuffs, possesses some trade; and corn, wood, and glass-ware are enumerated among the exports. N. Lat. 53. 50. E. Long. 13. 42.

ANCONA, a province of Italy, with the title of Marquisate, which is bounded by the gulf of Venice on the east, and is about 65 miles in length, and nearly 50 miles in breadth. The soil, which is fertile and well cultivated, produces abundance of corn, wine, hemp, and wax. The province is watered by numerous streams; the population exceeds 330,000; and Ancona, Ascoli, and Loretto, are some of its chief towns.

ANCONA, a flourishing sea-port town of Italy, and capital of the marquisate of the same name. Traditionary history ascribes its origin to a colony of Syracusans, whom the tyranny of Dionysius drove from their native country, 400 years before the Christian era. Ancona afterwards fell under the dominion of the Romans; was highly favoured by the emperor Trajan; and, by the improvements and benefits which it received from that prince, rose to great commercial prosperity. A splendid triumphal arch of beautiful marble was erected by the grateful inhabitants to commemorate his name. Soon after the commencement of the 18th century, Ancona, by the liberal policy of the popes, was declared a free port, with additional privileges; but, in 1797, it was seized by the French; and in 1799 it was recovered by the allied forces of Austria, Russia, and Turkey, after a severe siege and blockade.

Ancona presents a beautiful appearance when seen from the sea; some of its public edifices, particularly the exchange, were distinguished by their magnificence, but have been defaced or entirely demolished by the rude and unsparing hands of the French revolutionists; the population amounts to 20,000, and the chief exports are corn, wool, and silk. Ancona is 107 miles N.N.E. from Rome, and in N. Lat. 43° 58′, and E. Long. 13° 29′.

ANCUS MARTIUS, the fourth king of the Romans, and the grandson of Numa Pompilius, contributed greatly to the power and prosperity of his country, by the extension of its territory, and the enlargement of the city, and died about 615 years before the Christian era.

ANCYLE or ANCILE, a shield which it was pretended fell from heaven in the time of Numa Pompilius, and accompanied with a supernatural declaration that Rome should continue the sovereign of the world, as long as she retained this sacred gift. To obviate the risk of its loss, eleven shields were made exactly of the same form and appearance, and were formally deposited in the temple of Vesta, under the superintendance of twelve priests who were appointed to that service; and at the festival of the *ancylia*, or the 1st of March, the twelve shields were carried round the city in solemn procession.

ANDALUSIA, a province of Spain, which is bounded on the north by Estremadura and New Castile, by the Straits of Gibraltar and the Atlantic ocean on the south, and by the Portuguese territory on the west, is more than 300 miles in length and about 150 miles in breadth, and is distinguished by the fertility of its soil. This province is watered by the Guadalquiver. Its productions are corn, wine, oil, fruits of the richest kinds, sugar, barilla, and silk. The horses of Andalusia are celebrated as the best in Spain; and the sheep afford wool of an excellent quality. Mines of quicksilver, lead, and some other metals, have been discovered in the mountains. The air of this province is temperate and salubrious. The estimate of the population exceeds 1,200,000; Seville is the capital; and Cadiz, Cordova, and Xeres de la Frontera, are ranked among the chief towns.

ANDALUSIA, NEW, a district or division of Terra Firma, in South America, which is included under Spanish Guiana.

ANDAMAN ISLES, a cluster of islands in the bay of Bengal, and opposite to the coast of Malacca, two of which are distinguished by the name of Great and Little Andaman. The Great Andaman is about 140 miles in length, and about 20 in breadth, the coasts are deeply indented with creeks and arms of the sea, some of which form excellent harbours; much of the surface is covered with thick forests, among which ebony and the Nicobar bread-fruit trees are abundant, and the most common quadrupeds are rats, monkies, and wild hogs. The extent of the Little Andaman is stated at 25 miles in length and 15 in breadth. During the wet season these islands are exposed to incessant torrents of rain.

The inhabitants of the Andaman islands, the number of which is estimated at 2000, or 2500, are still in a condition of extreme barbarity; they depend chiefly on fishing for their precarious subsistence, and their huts, and implements, and utensils of every description, are of the rudest construction. They are altogether without clothing, and cover their bodies with a plaster of mud, which, being dried in the sun, defends them from the troublesome attacks of insects. They are generally of a diminutive stature, and their flat noses, thick lips, and woolly hair, indicate, as some suppose, their descent from an African race. Of late years a British settlement, to which convicts are transported from Bengal, has been established in the Great Andaman.

ANDELY, Great and Little, two towns in the department of Eure in France, the former situated on the banks of the Gambion, and the latter on the Seine. The population is about 4000. The woollen manufactures, which were established in the beginning of the fifteenth century, now afford active employment to 1000 persons; a copper foundery occupies the industry of another portion of the inhabitants, and Andely deserves notice as the birth-place of the celebrated painter Poussin.

ANDERAB, a rich and populous city of independent Tartary, situated on a river of the same name, and at the foot of the mountains which divide India and Persia from Great Buckharia. The only route to India is through this place. An oppressive duty of four per cent. on all goods in their passage, is a source of considerable revenue to the khan, or ruler of the province. *Lapis lazuli* is a production of the neighbouring mountains, and the scanty localities of this beautiful and sparingly distributed mineral have been magnified into the name of quarries.

ANDERNACH, the *Antoniacum* of the Romans, some of whose defensive works are still visible, is a town of Germany, formerly belonging to the electorate of Cologne, and, during the revolutionary extension of the French territory, included under the department of the Rhine and Moselle, is situated on the banks of the Rhine; has a considerable trade in pottery, timber, and millstones, and derives an ample revenue from the duties levied on vessels which navigate the river, and particularly from the immense rafts of timber which are conveyed down the Rhine to Holland.

ANDERO, Saint, or Santander, a sea-port town of Spain, on the Bay of Biscay. The population is estimated at 5000, a considerable proportion of whom are engaged in successful commerce; the harbour admits vessels of moderate burden, but the access to it is not very commodious; and the establishment of a royal dock-yard for building ships for the Spanish navy is now abandoned. N. Lat. 43°. 27′. W. Long. 4°.

ANDERSON, Alexander, an eminent mathematician, and an assiduous student of ancient geometry, who flourished about the beginning of the seventeenth century, was a native of Aberdeen, in Scotland, and in early life removed to Paris, where he became a teacher of mathematics. Mr Anderson was the author, or editor, of various works on the subjects of his favourite pursuits, chiefly relating to the more profound disquisitions of the ancient geometers; and in the latter character he published the works of Vieta, a celebrated French mathematician, to which he not only furnished an able preface, dedication, and appendix, but, by his learned commentaries, supplied what was defective, and illustrated what was obscure. The works now alluded to appeared between the years 1612 and 1619. But the scanty biography of this distinguished mathematician is equally silent in reference to the time of his death, and to the exact period of his birth.

A remarkable coincidence of kindred genius existed in the family of Anderson. His brother David, the proprietor of Finzaugh, a small estate in Aberdeenshire, was no mean proficient in mathematical and mechanical knowledge; and the daughter of David Anderson, who married the Reverend John Gregory of Drumoak, in the same county, was the mother of James Gregory, the inventor of the reflecting telescope. To the tuition of this lady, with what truth we know not, is ascribed that strong bias to abstract investigations, which seemed to become hereditary in her family, and continued long to associate the name of Gregory with the sublime departments of mathematical science.

ANDERSON, John, a learned philologist and naturalist, was descended from a Swedish family, who had settled in Hamburgh, and was born in that city in the year 1674. His early life was assiduously devoted to the acquisition of languages; and his knowledge of the Greek tongue was so profound and familiar, that when he travelled in Holland in the train of Peter the Great of Russia, the learned men of that country regarded him as a native of Greece. He was originally destined for the church, but his own inclination led him to the study of law, which he practised for some time as a profession after his return to his native city. For several years he executed the office of a public functionary of Hamburgh, was engaged in various political negociations, and in 1732 was raised to the dignity of chief magistrate. But the laborious duties of an active citizen did not altogether preclude him from the cultivation of science, and an occasional correspondence with Leibnitz, and other learned men. His death happened in 1743, and he left behind him various manuscripts on subjects of philology and political economy; but he is best known as the author of *A Natural History of Iceland and Greenland*, which appeared originally in the German language, and was afterwards translated into French. He contributed liberally to the enlargement and improvement of a public museum of natural history, which was established by his father at Hamburgh.

ANDERSON, Adam, author of a work on commerce, was a native of Scotland, which, it would appear, he had left in early life, for he was long employed as a clerk in the South-Sea House, was afterwards promoted to the office of chief clerk of the Stock and New Annuities, and was appointed a trustee for establishing the colony of Georgia in America. In fulfilling the duties of the different situations which he held, his attention was probably directed to the consideration of those topics which form the subject of his *Historical and Chronological Deduction of Trade and Commerce*, which was published in 1762, a very elaborate work, and the only literary production by which he is known. He died in 1775.

ANDERSON, Dr James, a distinguished writer on rural affairs and some branches of political economy, was born at Hermanston, a village near Edinburgh, in the year 1739, and was destined when very young, in consequence of the death of his parents, to the occupation and management of a small farm which had continued for several generations in the possession of the family. Guided by his own sagacity, or directed by the advice of friends, he saw the importance of general knowledge in conducting the complicated business of husbandry, and, among other acquirements, he bestowed a large share of his attention on chemistry, which he studied assiduously under the celebrated Cullen. At the age of fifteen he entered on active life, remained a few years on the possession long held by his ancestors, and removed to a large farm in Aberdeenshire, on which he resided for twenty years. In 1771 his *Essays on Planting* appeared periodically in the Edinburgh Weekly Magazine, under the signature of *Agricola*, and were published, in 1777, in a collected form. In 1780, he received from the University of Aberdeen, the honorary title of Doctor of Laws, and three years afterwards he returned to the vicinity of Edinburgh. A pamphlet, on the subject of the North British Fisheries, which he circulated among his friends, attracted the notice of Government, and, under the authority of the Lords of the Treasury, he surveyed, in 1784, the western coast of Scotland, with a view to the improvement of the fisheries and other departments of internal economy; and in the succeeding year, the substance of his Report of the Survey was published.

After the lapse of a few years, the literary labours of Dr Anderson took a wider range, when he commenced the *Bee*, a periodical work, which appeared in 1791, in weekly numbers, and swelled out to eighteen volumes 8vo, an unusual magnitude for such undertakings. But when it is known that a large proportion of its multifarious disquisitions were contributed by himself, further proof is not needed of the various acquirements and laborious industry of the author.

Dr Anderson fixed his residence in the neighbourhood of London, in 1797; and in 1799, he undertook another periodical work, under the title of *Recreations in Agriculture, Natural History, &c.* which he continued, by furnishing a considerable share from the stores of his own mind, till six volumes 8vo were completed. This was his last literary production, with the exception of Selections from his Correspondence with General Washington, and a pamphlet on the Causes and Means of obviating the Scarcity of Grain in Britain. After this publication ceased in 1802, the only subjects which seem to have occupied the attention of Dr Anderson, in his retreat at Isleworth, were the construction of a hot-house without artificial heat, experiments to determine the heat and moisture most suitable for different plants, and the means of destroying wasps to prevent their depredations on fruits. The method suggested by Dr Anderson, for the extermination of these destructive insects, was to discover and destroy the queens before they deposited their eggs in the early summer months; and for this purpose an association was formed and rewards offered for every queen wasp presented within a limited period. But the plan was either defective in its principle, or it was not pursued with sufficient zeal and perseverance; for it is not understood that the ravages of the wasp in that neighbourhood have at all diminished.

For some years previously to the close of life, Dr Anderson began to feel the infirmities of declining health. He died in October 1808, in the 69th year of his age. Of thirteen children, by his first wife, five sons and a daughter only survived him; and one of his sons, who became eminent as an engraver on wood, has since terminated his mortal career. His second wife was a widow lady in Isleworth.

Beside the works already noticed, Dr Anderson was the author of numerous productions, chiefly relating to rural economy, as well as of various memoirs on kindred topics, which appeared in periodical publications. All his writings bear the stamp of a vigorous understanding and a well-informed mind. The charge of prolixity which has sometimes been made is not altogether groundless; and some of his speculations may be pronounced fanciful, as in his treatise on peat-moss, which he attempts to prove derives its origin from the growth and increase of a living vegetable, and not from the decay of dead plants, according to the generally received and obvious opinion. Dr Anderson's claim to the discovery of the new mode of draining, for which a parliamentary reward was granted to Mr Elkington, has been stated in the chapter on Draining, under Agriculture.

ANDES, a chain of mountains in South America, which, by their vast extent and immense height, exceed every other elevated ridge in the Old World. This mountainous range stretches more than 4000 miles from the straits of Magellan, in the 53d degree of south latitude to the isthmus of Darien, which lies in the 8th degree of north latitude, and preserving a mean distance about 140 or 150 miles, runs nearly parallel to the western shores of the American continent. The chief information relative to the Andes is derived from the Academicians who visited these lofty regions in 1736, and more recently from the enterprising exertions of the adventurous and indefatigable Prussian Traveller, Humboldt, whose scientific descriptions have in some degree rendered Europeans familiar with the surprising features of this portion of the New World.

Andes.

Divisions of the Andes.—The great mountainous chain of the Andes presents a natural division into a principal and three subordinate ridges. The principal ridge runs from south to north, the whole length of South America, and the three subordinate branches pass off from the main trunk, nearly at right angles, penetrate far inland, in an easterly direction, and divide that wide continent into three immense vallies.

The grand primary ridge of the Andes divides to the southward of Cuenza, and continues double to the northward of Popayan, a distance of 500 miles; and in this double ridge is included the elevated plain of Quito. The western ridge in this part of its course is about 120 miles from the shores of the Pacific ocean. This long valley rarely exceeds the breadth of 20 miles, and in some places it is much narrower; but a fertile, well cultivated, and populous plain, raised to the astonishing elevation of between 8000 and 9000 feet above the level of the sea, presents a striking feature in the wonderful scenery of the American continent. As the principal mountains of the double ridge approach or recede from each other, they form small vallies, some of which are distinguished as the station of different towns or cities, as Cuenza, Riobamba, Latacunga, and Quito.

Principal mountains.—The lofty summits of the principal mountains of this portion of the Andes, which are invested with perpetual snow, exhibit another grand feature in the New World. Pinchinca, contiguous to the city of Quito, on the north, and, in a southward direction, Corazon, Ilinissa, Carguayraso, and, the loftiest of the whole, Chimborazo, are the chief mountains of the western ridge; and Cayamburo, Antisana, Cotopaxi, Tunguragua, Altair, and Sangai, form the highest summits of the mountainous boundary on the east and south.

Pinchinca.—This mountain has acquired scientific celebrity from being the station selected by one party of the academicians, who were engaged in 1736 in measuring a degree of the meridian. It is a volcanic mountain, and its crater, when visited by Condamine at the time alluded to, was extinct, and covered with snow; but in 1802, when it was examined by Humboldt, symptoms of activity appeared. On a rock projecting from the side of the crater, that adventurous traveller took his station to survey the dreadful gulf below. The mouth of the volcano presents a circular opening not less than a league in circumference. The interior of this huge excavation is dark and gloomy; but within its black walls the peaks of several mountains of inferior magnitude are distinctly seen. The observations of Humboldt fix the height of Pinchinca, above the level of the sea, to be about 15,000 feet.

The academicians, during their stay in this elevated station, experienced all the horrors of winter, with the rapid and singular contrast of an occasional glimpse of sunshine. The field-tents, which had hitherto served for their accommodation, were here altogether insufficient to protect them from the severity of the cold, or to resist the fury of the tempest. The whole party crowded into a single small hut, and, to supply them with light and heat, lamps were kept burning day and night. The wind blew with dreadful violence, and the accumulated fogs became so dense as to veil them at noon in the darkness of midnight. Sometimes the scene changed; the thick mists were seen collecting in regions far below them; the lightnings flashed through the dark clouds; and the distant roar of the thunder re-echoed from the surrounding mountains; while the air resumed its serenity, and the sun's rays darted a cheering influence on their dreary abode. But this was only a temporary cessation of the storm. The fogs again returned and gathered around denser and darker; the wind blew with redoubled rage; and the showers of hail and snow were almost incessant. In the midst of this tempestuous war of elements, the danger of being overwhelmed under a thick mass of snow, or of being swept down the precipice by the fury of the blast, alternately presented itself. The severity of the cold produced violent effects on the bodies of the travellers; their feet became inflamed and swelled, so that they could not walk without great pain; and the lips also inflamed, swelled, and bled, with the slightest motion.

Chimborazo.—Chimborazo rears its snowy head to the greatest height of all the mountains of the elevated ridge of the Andes. No traveller has yet reached its summit. The enterprising Humboldt, by pursuing his ascent along a ridge of volcanic rocks which were free from snow, was not more than 1400 feet from its loftiest pinnacle. Arriving at the altitude of 18,000 feet, his respiration was uneasy and laborious, from the thinness of the air; but, determined to accomplish his arduous and unparalleled undertaking, he was not deterred from proceeding, till a deep and impassable fissure, which crossed his path, precluded his farther progress, and forced him to abandon it in despair. In this dreary region of perpetual winter, no living sound was heard; all was melancholy, dismal, and silent; the scanty productions of vegetable life were limited to diminutive mosses; and the few rays of light, which occasionally penetrated the thick fogs, unveiled the horrors of the yawning abysses around. Scorified rocks and masses of pumice-stone, which were observed on different parts of the mountain, are considered as indications of volcanic agency; but no records are preserved of Chimborazo having been in a state of activity. The height of this mountain, estimated by the trigonometrical measurement of Humboldt, is stated at 3267 toises, or a little more than 20,000 feet.

Antisana.—In attempting to reach the summit of Antisana, Humboldt arrived at a higher point than the academicians. Having ascended more than 16,000 feet above the level of the sea, the air was so much rarified that the blood burst out from different parts of his face; all his attendants were seized with extreme debility, and one of them actually fell into a fainting fit. The barometer had sunk to 14 inches and 7 lines. Antisana, which is one of the mountains of the eastern ridge, is volcanic.

Cotopaxi.—Cotopaxi, the seat of another volcano, belongs to the eastern range; and its altitude, according to Condamine, falls little short of 18,000 feet. The first eruption of this volcano, of which any record is preserved, coincided nearly with the time of the Spanish invasion, and, it is said, facilitated the conquest

Andes. of that devoted country, in consequence of a prediction, current among the natives, that the period was now arrived when their land should be occupied by strangers; and regarding that natural event as a warning signal of the dreaded calamity, yielded up their territory an easy prey to their rapacious invaders. After the lapse of more than 200 years, indications of an approaching eruption were observed; and in 1743, when the flames burst out from various openings near the summit, they were immediately succeeded by a prodigious torrent of water, which swept off detached cottages, towns, and villages, in its irresistible course, and carried devastation and ruin far and wide. After a few days the torrent of water ceased to flow; but the flames, which continued longer, were accompanied with a tremendous noise, which was supposed to proceed from the violent rushing of the wind through the new openings of the mountain. Might it not, with more probability, be ascribed to the sudden conversion of a large quantity of water into vapour?

Sangai is another volcanic mountain, included in the double range, and is remarkable for the frightful sounds which are distinctly heard at the distance of 30 or 40 leagues, when it is in a state of activity. Altair and some others are also the seat of volcanoes; and Tunguragua, long celebrated for its hot springs, is the frequent resort of invalids from the surrounding country to enjoy the benefit of warm-bathing. The character of the American volcanoes is very different from those of Europe in the nature of the ejected matters. Immense torrents of mud and water take place of the ashes and lava which are discharged by the latter; and, what is not the least singular fact connected with the history of the volcanic eruptions of the New World, a particular kind of fish, to which Humboldt has given the name of *pimelodus cyclopum*, are sometimes thrown out in great numbers along with the mud and water. The origin of these fish, which has been the subject of speculation, is probably to be sought for in some of the lakes or rivers in the vicinity which have a communication with the excavated regions of the mountains by means of the numerous fissures by which they are traversed, or by temporary openings produced by earthquakes, which often accompany volcanoes.

Subordinate ridges.—Three subordinate branches, or *cordilleras*, according to the Spanish appellation, pass off from the grand primary chain of the Andes. The *first* branch, in tracing the great ridge from south to north, is the cordillera of *Chiquitos*, which traverses a province of the same name. Proceeding in its course eastward, this subordinate ridge forms a sweep between the 15th and 20th degree of south latitude, and connects, by a mountainous chain, that portion of the Andes which is contiguous to Chili and Peru on the west, with the elevated regions of Brazil and Paraguay on the east. The tributary streams of the La Plata flow down the southern side of this ridge; numerous rivers, which swell the waters of the Maragnon, have their sources on its northern declivity; and the *Pampas*, a dead flat, of immense extent, formed to a great depth of alluvial soil, and clothed with a luxuriant growth of tall coarse grass, which feeds innumerable multitudes of wild cattle, stretches to the southward of the cordillera of Chiquitos. Andes.

The middle branch, which is sent off from the principal ridge of the Andes, has been denominated by Humboldt the *cordillera of the cataracts of the Oronoco*. Of this elevated tract 600 miles were surveyed by that enterprising traveller; but the greater part of the chain consists of inaccessible regions, which are very little known. When it leaves the main ridge, the course is nearly eastward; about the fifth degree of north latitude it crosses the Oronoco, and takes a north-east direction towards the source of the river Caronis. Between the fourth and fifth degree the breadth is greatly diminished; and stretching to the south and south-east, joins the granitic mountains of Guiana. The scanty information which has been obtained concerning these extensive wilds, is derived from the singular adventures of a Spaniard, who, being familiar with the language of the different native tribes, assumed the Indian garb, travelled unsuspected among the ferocious inhabitants, and having reached the lake of Parimé and the Amazons river, returned in safety. The fabled account of *El Dorado*, or the golden mountain, which had long gratified the credulity of ignorance, was corrected and explained by his observations, from which it appears, that this far-famed mountain, which stands on the banks of the Mao, a tributary stream of the Oronoco, is composed chiefly of a shining micaceous schistus. The mean altitude of this chain is about 4000 feet above the level of the sea; but Duida, a volcanic mountain, and the highest of the whole ridge, rears its lofty head to more than 8000 feet. This cordillera is most abrupt and precipitous on the south; and through the valley, of which this chain forms the northern boundary, and which is covered with impenetrable forests, the Maragnon rolls its mighty stream.

The most northerly of the secondary branches, is the highest and the narrowest. It passes off from the Andes near Popayan, proceeds in a northerly course towards the Caribbæan sea, approaching the lake Maracaybo, turns suddenly to the east, and advances along the coast to Trinidad. Some of the mountains of this subordinate ridge are remarkable for their elevation. The *Sierra Nevada*, or, as its name imports, snowy summit of St Martha, in 10° of north latitude, rises to the height of nearly 14,000 feet above the level of the sea; and the altitude of the *Sierra Nevada* of Merida, in north latitude $8\frac{1}{2}$°, exceeds 15,000; and although they are covered with perpetual snow, springs of boiling sulphureous water continually flow from their sides. From that part of the chain which stretches between Merida and its termination near Trinidad, two parallel ridges branch off, and form the boundaries of three vallies of unequal elevation, which are arranged from east to west, and seem to have been the beds of ancient lakes. The valley of the Caraccas, measured by Humboldt, barometrically, is more than 2500 feet above the level of the sea; the valley of Aragua is lower, and is estimated at 1300 feet; while the valley or plain of Monai rises only about 500 or 600 feet above the surface of the ocean. Another lofty part of this chain is what is denominated the *Silla* or Saddle of the Caraccas, whose height determined by Humboldt, by barometrical observations, exceeds 8000 feet; but the mean altitude of the whole cordillera is between 4000 and 5000 feet.

Mineral productions.—The mineral riches of this remarkable portion of the globe roused the avarice of the Spaniards, and urged them, through blood and carnage, to the subjugation, and in many places the utter extermination of the native inhabitants. With the exception of lead, the Andes are the repositories of almost every other metal; but of the precious metals silver has been always the most abundant, and still affords a large annual supply to the Spanish treasury.

The rocks which compose the stupendous ridges of the Andes, belong partly to the primary, and partly to the secondary class; granite, quartz, micaceous, and argillaceous schistus, are the prevailing rocks, in a large proportion both of the principal and subordinate chains. In some places the primitive rocks are covered with sand-stone, lime-stone, and small patches of gypsum. But the geological constitution of the central Andes exhibits peculiarities in the immense thickness of the strata, which find no counterpart in any other part of the world. The loftiest summits of the principal ridge are entirely composed of porphyry, which is distributed in enormous masses of more than 10,000 feet thick; the thickness of a stratum of sand-stone is stated at 5000 feet, and that of a huge mass of pure quartz exceeds 9000 feet; and the basalt of Pinchinca is deposited at an elevation exceeding 15,000 feet, which is 10,000 feet higher than any locality of that kind of rock yet discovered in the Old World.

Fissures.—The Andes are not more distinguished from the mountains of other parts of the globe by their great extent and elevation, than by the remarkable fissures with which they are traversed. Perpendicular rents or fissures are not uncommon in basaltic regions. Hooker, who visited Iceland in 1809, mentions various chasms which he met with in that rugged country, one of which he describes as 200 feet high, and about 20 yards broad. Through this chasm the traveller passes in his progress to one quarter of the island. But the rocky chasms of Iceland, with all their horrors, dwindle into tameness and insignificance, when compared with the tremendous rents of the Andes, some of which are nearly a mile in depth. Some of these fissures have natural bridges, which afford an easy communication to the traveller. A bridge of this description, which connects the two sides of a rent called Icononzo, and through which a river flows from the mountains, is 50 feet long, 40 feet broad, and at its middle part about eight feet in thickness. The height of this arch above the surface of the stream is not less than 300 feet, and about 60 feet a smaller arch, consisting of three masses of stone, is projected over the same fissure. The Peruvians sometimes form a communication with the opposite sides of these rents, by means of hanging bridges, constructed of ropes, manufactured from the strong fibres of the American aloe, and covered with reeds; and to render them more secure, a border of a kind of basket work is sometimes added.

Climate.—Every variety of climate prevails in the Andes. Perpetual spring reigns in the lower regions, and the glowing influence of a vertical sun produces the gayest and most luxuriant vegetation; the dreary abode of winter is for ever fixed in the loftier summits, from which all vegetable and animal life is excluded; while the intermediate regions present all the diversified shades of the milder and more temperate portions of the earth.

The line of perpetual snow, or that point where it freezes during some part of every day throughout the whole year, is at the height of about 15,000 feet above the level of the sea, under the equator; and it has this peculiarity, that the uniformity of temperature which prevails in these regions, preserves this line always at the same height.—The reader's trouble will be amply rewarded, by the acquisition of much curious information concerning these stupendous mountains, in the perusal of Ulloa's Travels in South America, and of the later work of Humboldt on the same subject.

ANDOVER, a borough town of Hampshire, in England, with a population exceeding 3000, has some trade in malt, and a manufacture of shalloon; is noted for its excellent inns, and the traces of Roman encampments which are still visible in the vicinity. Andover is on the great road between Exeter and Plymouth, and is about 65 miles west from London, and 18 miles E. N. E. from Salisbury.

ANDRACHNE, or Base Orpine, is a genus of plants belonging to the Monoecia class.

ANDRENOVIAN ISLANDS, a group of islands forming part of the chain which is included under the general denomination of Aleutian islands, and which stretches between the western shores of America and the eastern continent of Asia in the Northern ocean. See Aleutian Islands.

ANDREW, the Apostle, the son of Jonas, and the brother of Simon Peter, was a native of Bethsaida in Galilee, followed the occupation of a fisherman, and had been a disciple of John the Baptist. Convinced of the divine mission of Christ, in consequence of the miraculous draught of fishes, they forsook their employment to preach and propagate his doctrine. After the ascension of Jesus Christ, the apostles determined by lot to what countries their labours should be severally directed. The apostle Andrew was appointed to Scythia and the adjoining regions; and proceeding on his destined mission, he journeyed through various parts of Greece, and had reached Patræ, a city of Achaia, then a Roman province, where he was apprehended by the command of the governor, severely scourged, and condemned to the death of the cross, the form of which is said to have been that of the letter X, and hence called St Andrew's cross. Bound with cords instead of being fastened with nails, he lingered two days in this painful situation before he expired. He suffered martyrdom on the 30th November, the day on which his festival is celebrated in those churches in which such observances are attended to; but the year is undetermined. His body was afterwards removed by the Emperor

Andrews.

Constantine to the great church at Constantinople, which he erected in honour of the apostles.

ANDREWS, James Pettit, a historian and miscellaneous author, was a native of Berkshire in England, and was born in the year 1737, spent part of his early life in the militia regiment of his own county, and was afterwards appointed a commissioner of police in London, the duties of which he faithfully discharged till his death. The first of his literary productions was a biographical sketch of his friend and relation, Mr Penrose, to an edition of whose poems, published in 1781, it was prefixed as a prefatory discourse. A pamphlet in behalf of Chimney-sweepers Apprentices, exposing the cruelty and barbarity of their treatment, which appeared in 1788, was followed in the succeeding year by *Anecdotes Ancient and Modern*, and by his *History of Great Britain, connected with the Chronology of Europe*, 2 vols. 4to. in 1794 and 1795; which latter is the most elaborate work of the author, and is conducted on a peculiar plan, which is well calculated to exhibit a chronological view of European history. While the history of England is detailed on one page, the opposite page presents a brief notice of the more important cotemporary events of the principal nations of Europe; and longer narratives of the state of government, manners, literature, and science, are occasionally interposed in the form of appendix. The work commences with the period of the Roman invasion of Britain, and terminates with the accession of Edward VI. Mr Andrews published, in 1796, a continuation of *Henry's History of Britain*, in one 4to volume. Beside the works now enumerated, which afford ample proof of industry and research, he was the author of various literary productions of a more fugitive nature. Mr Andrews died in August 1797, in the 60th year of his age.

ANDREWS, St., an ancient borough and seaport town of Fifeshire, in Scotland, and the seat of the oldest of the four Scottish universities, stands on a rocky promontory at the bottom of a bay of the same name, and on the south side of the frith of Tay.

Origin and Antiquities.—According to the traditionary legend, Regulus, a Greek monk, warned by a vision from heaven to preach the gospel to the Picts of Britain, left his native country towards the end of the 4th century, and having encountered a tempestuous voyage, was shipwrecked in the bay of St Andrews. But the Pictish king received the saint hospitably, embraced Christianity along with many of his subjects, gave him one of his royal palaces for a residence, and built a church bearing the name of St Regulus or St Rule, from that of the saint; and to which it is said, but surely with little probability, that part of the walls, and the tower, which is 20 feet square and 103 feet in height, yet remaining, and still a solid structure, belonged. The name of St Andrews is derived from the relics of the apostle Andrew, which Regulus brought with him into the country; and when the Picts were subdued by the Scots, the seat of government was transferred, in 840, from Abernethy, the capital of the Pictish kingdom, to St Andrews.

Andrews.

The priory, to which great privileges and rich revenues were annexed, was founded in 1120. But, excepting the surrounding wall, scarcely any other vestiges remain. The piety of succeeding ages extended the religious establishments of St Andrews by the erection of two convents, of which the only remains are part of a chapel, which is deservedly admired as a fine specimen of Gothic architecture. The cathedral church, begun in 1159, was not finally completed till 157 years had elapsed, and was demolished by the misguided fury of the populace, inflamed by a sermon of the great reformer John Knox against idolatry, exactly at the end of four centuries from the commencement of the edifice. The mouldering remains of the east and west ends and part of the south wall, present to the contemplative mind a melancholy contrast with its former magnificence. St Andrews was erected into an archbishoprick after the middle of the 15th century, and continued the seat of the primate of Scotland during the episcopal establishment.

The castle, of which little now remains, was built in the 12th century, on a rock projecting into the sea, and was long conspicuous in Scottish history. It was the usual residence of the prelates of St Andrews, the birth place of James III. of Scotland, and the bloody scene of the murder of Cardinal Beaton, by a party of the covenanters, which was regarded as an act of retributive justice for his cruelty in condemning to the stake George Wishart, a protestant reformer, and witnessing from a window, which is still pointed out, the execution of the horrid sentence.

University.—The university of St Andrews, founded by Bishop Wardlaw in 1411, included formerly three colleges: 1. St Salvator's, founded by Bishop Kennedy in 1458; 2. St Leonard's, founded by Prior Hepburn in 1522; and, 3. St Mary's, or the New College, from its later erection, begun by James and David Beaton, and finally established by Archbishop Hamilton, in 1553. St Salvator's and St Leonard's colleges were conjoined in 1747 under the name of the *United College*; and the buildings of the latter were sold and converted to private use. Divinity, Church history, and Oriental languages only are taught in St Mary's college; but in the United College, beside the ancient languages, the usual academical courses of philosophy are delivered. The number of students in both colleges rarely exceeds a hundred. The church of St Salvator is adorned with a fine Gothic tomb consecrated to the memory of the founder. In this tomb, as tradition reports, six maces of magnificent workmanship, supposed to have been secreted for preservation in times of civil dissension, were found concealed about the end of the 17th century, one of which was presented to each of the other three Scottish universities, and the remaining three were retained.

Modern state.—The situation of St Andrews, on a steep, projecting promontory, with a fertile country to the westward, and extensive downs, or *links*, on the north and south, is striking and picturesque; and buildings, venerable from antiquity, or ruined towers, rearing their crumbling heads among edifices of modern form and construction, exhibit altogether a singular feature in its character. The three principal streets, which run from east to west, are intersected by smaller lanes. The buildings of the Philosophy, or United college, are in North Street; and those appropriated to St Mary's, or the Divinity college, are in South Street. This town was erected by David I. in 1140, into a royal borough; and the charter of Malcolm II. written on a small slip of parchment, is still preserved.

With a population not much exceeding 3000, manufactures must be limited. The making of golf-balls employs a few hands; and in 1793 the manufacture of sailcloth, of a particular fabric for strength and durability, was introduced by Mr Dempster, the inventor, who obtained a patent for his improvement. At one period the trade of St Andrews was considerable; but it has now declined, and the few vessels belonging to the port are employed in the coasting trade. In comparing the present state with the more splendid and flourishing periods of its history, it has been stated that 70 bakers were required to supply it with bread, while nine or ten in the present day are quite adequate to the demand. Archery once flourished, but has now gone into disuse; and golf and foot-ball are now said to be the chief amusements of the inhabitants. It is curious to observe, that the two latter games were formally prohibited by an act of the legislature in the time of James II., as hurtful and unprofitable. St Andrews is in N. Lat. 56° 19′, and in W. Long. 2° 50′, and 38 miles N. E. from Edinburgh.

ANDREWS, St. or Andre's, St. an island in the Caribbæan sea, opposite to the province of Nicaragua in Mexico, and remarkable for the magnitude of the cedar trees, and not less so for the absence of birds and beasts from the land, and fish from the rivers; an assertion which has probably proceeded from careless or inaccurate observation, and requires farther investigation to be fully verified.

ANDROIDES, a machine in the human form, which, by means of mechanical contrivances, performs the motions or actions of man; such were the flute-player of M. Vaucanson, and the chess-player of M. De Kempelen, which were exhibited some years ago in different parts of Europe, and more lately the figure of a young lady which plays the forte-piano, the magician, and some others, constructed by M. Maillardet, a most ingenious Swiss artisan. See Automaton.

ANDROMEDA, according to fabulous history, was the daughter of Cepheus, a king of Ethiopia; and Cassiopeia, the mother, vain of her beauty, thought herself entitled to be preferred to Juno or the Nereids; Neptune, as a punishment, inundated the kingdom, and let loose a sea-monster to ravage the country. The response of the oracle declared, that the calamity could only be averted by exposing Andromeda to be devoured by the monster. She was chained to a rock, delivered by Perseus, afterwards became his wife, and was translated to the heavens by Minerva.

ANDROMEDA, a constellation of the northern hemisphere, near Cassiopeia and Perseus, the body of which is distinguished by three brilliant stars disposed in the form of an arch, and nearly equi-distant from each other.

ANDROMEDA, or Marsh Cistus, a genus of plants belonging to the Decandria class, of which one beautiful species, *polifolia*, is a native of marshy places in Britain.

ANDROPHAGI, an appellation of similar import with Anthropophagi, or *man-eaters*, according to the Greek derivation, was applied, by some ancient writers, to a nation contiguous to Scythia. It has been found to be the practice of many barbarous nations to drink the blood and to eat a portion of the flesh of their enemies taken in war; but otherwise the name is not strictly applicable to any race of human beings who subsist on the bodies of their own species.

ANDROPOGON, or Man's Beard, a genus of plants belonging to the Polygamia class.

ANDROS, or Andro, one of the ancient Cyclades, or cluster of islands in the Archipelago, is conspicuous in history on account of the inhabitants joining the Persians when Xerxes invaded Greece; of their resistance to the Athenians; of their conquest by Alexander the Great, and of their submission to the Roman dominion. This island, which is about 90 miles in circumference, is now subject to the Turks; some parts are mountainous, but the plains are well watered and fertile; it produces grain, wine, and oil, honey, wax, cotton, and fruits; the population, distributed into numerous villages throughout the island, is about 12,000; and it is in N. Lat. 37° 50′ and E. Long. 25° 25′.

ANDROSACE, a genus of plants belonging to the Pentandria class.

ANDRYALA, or Downy Sow-thistle, a genus of plants belonging to the Syngenesia class.

ANDUXAR, or Andujar, a town of the province of Jaen in Spain, stands on a plain on the banks of the Guadalquiver, is adorned with some beautiful churches and religious houses, has a population which exceeds 2000, with some trade in silk; the surrounding country abounds in grain, wine, oil, and fruits; and it is 40 miles east from Cordova.

ANDUZE, a town of the Cevennes, or department of Garde in France, with a population of 5000, and manufactures of woollen stuffs, silk stockings, and hats. It is 27 miles distant from Montpelier, and 21 miles from Nismes.

ANEMOMETER, an instrument for measuring the force and velocity of the wind. See Meteorology.

ANEMONE, or Wind-flower, a genus of plants belonging to the Polyandria class.

ANEMONE, Sea, the trivial name of the genus Actinia, or animal flower. See Helminthology.

ANEMOSCOPE, an instrument for observing the direction of the wind, of which the vane, constructed of a thin plate of metal, moving on an upright rod, and usually fixed on the top of lofty buildings, as spires and towers, is an example.

ANETHUM, Dill and Fennel, a genus of plants belonging to the Pentandria class.

ANEURISM, from the Greek word which signifies *swelling*, is the morbid dilatation of an artery, which for its cure requires a surgical operation.

Angel.

ANGEIOLOGY, derived from two Greek words, which signify *vessel* and *discourse*, is that part of anatomy which treats of the blood-vessels and lymphatics.

ANGEL, an order of created intelligences, superior to man. That there is such an order, we are expressly informed by the inspired writers; and, in reasoning from analogy on the subject, we are led to the same conclusion. So vast is the distance of what is finite and partly material, from what is infinite and wholly immaterial, that to suppose ourselves the next in rank to the eternal and incomprehensible God, would be to admit a chasm in the chain of existence, a chasm not sanctioned by that regular gradation downward from the place which we hold, to that of the passive inanimate objects which are scattered around us. Hence a class of beings, purely spiritual, seems necessary to form the connecting link between us and the great Creator. But though divested of all corporeal substance, as they certainly must be, notwithstanding the Christian fathers and scholastic divines have generally ascribed to them thin, ethereal, or fiery bodies, they have, when occasion required, become visible to man, by the assumption of a human or other appearance.

At what particular period angels were created, we are not told. Yet it is evident they were prior to the formation of the earth; for when the Almighty Architect laid its foundations "the morning stars sang together, and all the sons of God shouted for joy." It is maintained by St Jerome, and the author of the book *De Trinitate*, among the early Christian writers, and by Burnet and Stackhouse, among the moderns, that they were attendants in the court of heaven long before this planetary system sprang from the hands of God. To this it is objected: If the term "beginning," which Moses employs as the date of the creation, signifies the commencement of *time*, and this obviously is the only meaning of which it is susceptible, then to ascend a step higher in the scale of duration is to go beyond the bounds of finitude, and to enter on the regions of eternity; and, accordingly, to deny that angels were produced within the six days on which the other works of God were achieved, is virtually to assert that *a parte ante* they are eternal, an attribute peculiar to deity alone, and altogether inapplicable to limited and dependent beings. Besides, on giving to them such an antiquity, what comes of the argument, so much insisted on in scripture, for the pre-existence and divinity of Christ, "who was before all things," and "without whom was not any thing made that was made?" We must, therefore, either allow that the origin of angels is included in the Mosaic account, or adopt a sentiment which proves too much. Indeed, the most probable opinion is, that they were made on the first day, along with the heavens, and that they were present, chanting their songs of exultation and praise at every successive manifestation of creating power.

According to sacred scripture, the angels, taken collectively, constitute an immense multitude. Daniel in his vision saw "thousand thousands," of them ministering to "the Ancient of Days;" and our Lord declared, that if he chose to decline his sufferings, he could call from heaven "more than twelve legions" of them to his assistance, that is, upwards of 78,000, estimating the Roman legion at 6500 men. Nay, in reference to human arithmetic and human conception, an apostle styles them "an innumerable company."

Different gradations have been assigned to these celestial beings. By the Jews they are arranged into *four* orders, over which Michael, Gabriel, Uriel, and Raphael respectively preside; by Dionysius the Areopagite, and after him the Roman Catholic writers, into *nine* orders, three of which form a hierarchy, namely, seraphim, cherubim, and thrones,—dominions, principalities, and powers,—virtues, archangels, and angels; and by Mr Mede and others into *seven* orders, with an archangel at the head of each, as designed by the seven lamps in the Jewish tabernacle before the mercy-seat, and by the seven spirits of God sent forth into all the earth. But, while the volume of inspiration countenances a diversity of rank and dignity in the angelic host, such distributions and arrangements of them are mere conjectures.

Angels, as the name in the original indicates, are envoys or messengers; and, in various parts of the sacred writings, they are represented, not only as standing before God, performing solemn acts of praise and adoration, but as waiting in readiness to obey his commands. Hence they are called "ministers who do his pleasure," and "ministering spirits, who are sent forth to minister for them who shall be heirs of salvation." In the zealous discharge of their duties, they appeared to Jacob in his dream at Bethel, as "ascending and descending" on the ladder which he beheld stretched from heaven to earth; *ascending*, to bear the prayers of the saints before the throne, and to report the performance of their own services; and, intrusted with fresh commissions, *descending*, to bestow the favours and to execute the mandates of the Most High. It has been an opinion generally received among Jews and Christians, that empires, kingdoms, and individual men have their guardian angels; an opinion by no means unfounded in the word of God, Psal. xxxiv. 7.; Eccles. v. 6.; Dan. x. 3.; Matth. xviii. 10.; Acts xii. 15. The heathens also believed, that nations, cities, houses, and persons have their tutelary *genii*.

Angels, of all the creatures in the universe, have the nearest resemblance to Jehovah; and are, on this account, sometimes denominated *gods*. They are perfect in holiness, having their thoughts, desires, affections, and conduct duly regulated by the laws of righteousness and truth. Their knowledge, resulting from immediate intuition, the disclosures of revelation, and the long experience of nearly 6000 years, is very extensive; but being still circumscribed, there are many things of which they are entirely ignorant; and though not omnipotent, their strength is so prodigious, that no material substance can resist or impede their operations. We read of their bursting open the doors of the prison, of their shutting the mouths of furious lions, and of their quenching the violence of the fiery furnace.

But it must be remarked, that, not long before the fall of Adam, occasioned by their instrumentality, a revolt took place among the angelic spirits; and those who kept not their first estate were expelled from heaven, and consigned to the abodes of misery, where they are reserved in chains unto the judgment of the great day. How many of them rebelled against the Eternal, is a point on which we have no specific information; yet the number must be considerable, since it is sufficient to constitute a kingdom, under the government of a prince, named Satan, Beelzebub, or the Devil. They are distinguished by an apostle into principalities, powers, rulers of the darkness of this world, and spiritual wickednesses in high places. Nor do we know what the particular crime was through which they forfeited their honour and their happiness. It is commonly supposed to have been *pride* or *envy*: the Mahometans say, it was their refusing to do homage to the first man. Yet, of this we are certain, that they are the enemies of all good; that their hearts rankle with the blackest malignity; and that their unwearied study is to produce anarchy, desolation, and wretchedness in the creation of God. The inimitable poet, Milton, in his "Paradise Lost," thus describes the apostasy, character, and punishment of the archfiend and his associates:

The infernal serpent; he it was, whose guile,
Stirr'd up with envy and revenge, deceiv'd
The mother of mankind, what time his pride
Had cast him out of heaven, with all his host
Of rebel angels; by whose aid, aspiring
To set himself in glory above his peers,
He trusted to have equall'd the Most High,
If he oppos'd: and with ambitious aim
Against the throne and monarchy of God
Rais'd impious war in heaven, and battle proud,
With vain attempt. Him the Almighty power
Hurl'd headlong flaming from the ethereal sky,
With hideous ruin and combustion, down
To bottomless perdition; there to dwell
In adamantine chains and penal fire,
Who durst defy the Omnipotent to arms.

But there are some who deny the existence of these wicked spirits, and maintain, that wherever they are mentioned in scripture, we are to understand only a personification of the abstract principle of evil.

ANGEL-FISH, a species of *Squalus*. See ICHTHYOLOGY.

ANGELICA, a genus of plants belonging to the Pentandria class.

ANGELO, MICHAEL, the name of several Italian artists who flourished in the 16th and 17th centuries. The most distinguished were Michael Angelo Buonarotti, celebrated as a painter, sculptor, and architect; and Michael Angelo de Caravaggio, who rose to eminence as a painter. See BUONAROTTI.

ANGELOS, PUEBLA DE LOS, or City of the Angels, the capital of the province of Tlascala in Mexico, is described as one of the most flourishing towns of South America. A spacious square in the centre of the city is occupied on one side by a magnificent cathedral, and on the other three sides by elegant and uniform buildings; and from this square many broad and regular streets proceed in various directions. It contains numerous churches, which are distinguished by their splendour, two colleges, and many convents and nunneries. The population is stated at 60,000, variously occupied in manufactures of cotton cloths, hats, glass, fine earthen ware, swords, soap, and in the coinage of the silver from the mines of Zacatecas, which this town shares with Mexico, from which it is 22 leagues distant to the south-east.

ANGER, a strong emotion excited in the mind, the character of which is a propensity, or feeling, which prompts to repel an injury, and to avenge it on the offending party. When this emotion is restrained in its operation, it is distinguished by the name of *resentment*; but when it bursts out into the determined purpose of inflicting punishment on the offender, it is denominated *revenge*. Moralists and divines have distinguished anger into *deliberative*, or rational, and *instinctive*. The first is an important principle, implanted in the human mind, and intended, by the natural expression with which the emotion is accompanied, to protect from injury, or to denote, by suitable marks of disapprobation, the feeling excited by offences received. The second, or what is called instinctive anger, is a principle which man possesses in common with the inferior animals, and leads to acts of immediate revenge on the objects of offence. It has been observed, that anger is not altogether a selfish passion; for it is excited by the injuries offered to others as well as to ourselves; and hence it seems designed, by the Author of nature, to rouse us to vigorous action, not only in our own defence, but to interest us in the defence and protection of others who are injured and helpless. The emotion of anger, then, is a powerful principle in the constitution of man, and well calculated for his protection, or for the defence of others; but the excess of this feeling, as well as of every other interwoven in the human frame, is blameable and degrading to the character of a moral agent; and in this view the apostolic precept, 'Be ye angry, and sin not,' is to be understood.

ANGERMANNIA, or ANGERMANNLAND, a mountainous province of Sweden, bounded on the north by Lapland and Bothnia, on the east by the gulf of Bothnia, and partly on the west by Norway, contains about 80 square miles. In some places the forests are extensive; and in others the soil is fertile, and produces corn and flax. A river of the same name, one of the largest in the kingdom, and partly navigable, traverses the province. Iron ores are abundant; and some ores of copper have been wrought. The manufacture of linen, and other cloths, has been established on a limited scale; and Hermosand, a small place, is the only town of the province.

ANGERS, an ancient city of France, and capital of the former duchy of Anjou, now of the department of Maine and Loire, stands on the banks of the river Maine, which traverses the city. Angers was the frequent scene of warfare between the French and English; and the ruined towers and mouldering walls of the castle, which was reared on a projecting rock in the 13th century, still attest the strength of its ancient military defences. The cathedral is a magnificent structure, and presents some peculiarities in its architecture which have been greatly admired. The university was established about the middle of the 13th century, and the academy of Belles Lettres towards the end of the 17th century. The population, in the 17th century, amounted to 50,000; but the impolitic revocation of the edict of Nantes, which thinned France of its inhabitants, reduced Angers to 36,000 in 1697; and now it can scarcely reckon more than 30,000. The chief manufactures are linen, woollen stuffs, and wax candles; and white wines, grain, flax, and fruits, are the principal matters of commercial enterprise. N. Lat. 47° 28'. W. Long. 0° 33'.

ANGIOSPERMIA, from two Greek words, signifying a *vessel* and *seed*, is one of the orders of the class Didynamia in the Linnæan system of Botany. See BOTANY.

ANGLE, is the inclination of two lines meeting each other in a point, or the divergence or separation of two straight lines.

ANGLER, a species of fish belonging to the genus Lophius. See Lophius, under ICHTHYOLOGY.

ANGLES, called *Angli* by the Roman historian Tacitus, were an ancient German nation, who migrated to the territories of Denmark, afterwards invaded Britain, and subdued great part of the country, and it is supposed gave the name of *Anglia* or *England*, to the southern division of the island.

ANGLESEA, or ANGLESEY, an island and county of North Wales, is separated from Caernarvonshire by the narrow strait called Menai, and is about 24 miles long and 18 broad. The eastern shores are adorned with elegant mansions and thriving plantations; but the island in general is destitute of wood. The hills, which have no great elevation, are chiefly composed of limestone and argillaceous schistus, and they give origin to numerous small streams which water the vallies.

The soil is fertile, and produces such abundance of grain as to afford, in favourable seasons, a considerable exportation; and the pastures annually supply the English market with 8000 or 10,000 head of cattle, 5000 or 6000 sheep, and an equal number of swine. The population, estimated by the number of houses, in 1563, amounted to about 10,000; in 1776, from a similar estimate, the number had nearly doubled; in 1801 it had increased to nearly 34,000; and, in 1811, to 37,000. The island is divided into 74 parishes, and Beaumaris is the principal town.

Anglesea is the Mona of the ancient Romans, the Mon or Moneg of the Welsh, and was the residence of the chief priest of the Druids before the Roman invasion. In several places circles of stones, which are supposed to be the remains of Druidical monuments, are still visible. The Romans attacked the Druids in their sacred retreat in the 59th year of the Christian æra, vanquished the armies of the Britons, and destroyed the consecrated groves.

The mineral productions of Anglesea form the most important feature in the later period of its history. The discovery of masses of lead and copper, and of an ancient smelting hearth, is an indication of the existence of mining operations in this island at a remote period; but the commencement of the Pary's mountain establishment, in 1768, was the consequence of a new discovery, and has proved to the proprietors one of the most beneficial concerns in the kingdom. The body of Pary's mountain, which belongs to Lord Uxbridge and the Reverend Mr Hughes, and is about a mile in length, is chiefly composed of copper ore, the greatest part of which is dug out in the manner of an open quarry; for the rock of aluminous schistus forms little more than the external covering to the accumulated mass of ore. Two quarries or mines are wrought, and in some places have been carried to the depth of 50 fathoms. Including the smelters, 1300 men were at one time employed at both mines, and from 50,000 to 80,000 tons of ore were annually dug out; but the mines are now far less productive, and scarcely afford occupation to half the number of workmen. The varieties of ores are, native copper, in small quantity; black ore, a mixture of galena, calamine and a little silver; green and blue carbonate of copper; and copper pyrites, which is most abundant. The sulphate of copper, which is dissolved in the water of the mines, is precipitated by means of iron, and affords a large proportion of pure copper, which is carefully collected. Alum and green vitriol are manufactured to a limited extent from the materials furnished by the mines of Pary's mountain.

ANGLING, is the art of fishing with a rod, to which are attached a line fitted with a hook and bait, which latter is either natural or artificial. See FISHING.

ANGLO-CALVINISTS, an appellation by which those members of the church of England are distinguished whose opinions coincide with those of other Calvinists, excepting in matters relative to ecclesiastical government.

ANGLO-SAXON, is an appellation applied to the language spoken by the English Saxons, in opposition to the true Saxon and the modern English. The same designation is given to the people who spoke this language, and who invaded and conquered England after the departure of the Romans. The first invasion of England by the Anglo-Saxons took place in the middle of the fifth century; and, after a struggle of 135 years, when the oppressed and dispirited Britons were driven to the mountainous fastnesses of Cornwall and Wales, seven different kingdoms were at last established, a constitution which is well-known in English history, under the denomination of the *Heptarchy*. The kingdoms of the heptarchy were united, in 827, under Egbert, who was crowned king of England, and the Anglo-Saxon government continued during a period of 239 years, when the Norman race of kings commenced in the person of William the Conqueror, who invaded Britain in 1066, and, after obtaining a complete victory over Harold, established himself on the throne.

ANGOLA, formerly called Abonda, is a kingdom of Africa, stretching 480 miles along the western coast, and between the 8th and 16th degrees of south latitude. Excepting along the sea-coast, Angola presents a mountainous aspect; and in some places the summits of the mountains are so elevated as to be covered with snow in certain seasons of the year. The Danda and Coanza, which are the principal rivers, are of considerable magnitude, and are navigable for thirty or forty leagues from their junction with the Atlantic ocean. The soil on their banks is rich and fertile; in some places it is well cultivated, and yields abundant crops of millet, Indian corn, and other kinds of grain. The chief town of the kingdom of Angola is San Paulo de Loanda, which stands about twelve leagues to the north of the river Coanza in the province of Loanda. It was begun by the Portuguese about 1578, contains some good houses, with a cathedral and convent, and includes a motley population of Christians, pagans, and slaves, amounting to 12,000 or 15,000. It is the see of a bishop, and the residence of the Portuguese governor.

The Portuguese very early established their authority in the kingdom of Angola, and through the influence of their agents, the Jesuits, succeeded in forming alliances with the barbarous native sovereigns, and thus acquired numerous facilities of carrying on trade, and especially the slave trade which was probably one of the chief objects of maintaining a tedious struggle in defence of their settlements. The detailed narratives which have appeared of the transactions of the Portuguese in this part of Africa, are filled with accounts of pretended conversions of the natives to Christianity; of their apostasy to the rites of paganism; of their treacheries and murders; and all this under the formal dignity of history belonging only to civilized nations, while it appears that the people of Angola have made no farther advancement in the arts of life than any other of the African tribes.

ANGOLA, or Pigeon-pea, is a species of Cytisus, the *cytisus cajan*, Lin. which is much cultivated in Jamaica for the table, is equal to the English pea when in the green state, and when it is old forms an excellent ingredient in soups; is sometimes called the *Christmas* pea, from bearing at that season, and sometimes the *seven-years* pea, from the plant continuing productive for that period.

ANGORA, or Angura, the ancient Ancyra, the chief city of Galatia, is a town of Natolia, a province of Asiatic Turkey, and 212 miles E.S.E. from Constantinople. The fragments of broken pillars and marble ornaments, which are seen intermixed with the stones of which the walls and houses are constructed and cemented with mud, present a melancholy picture of the remains of its ancient magnificence. Angora stands in an elevated region, is subject to the Turks, and has been long celebrated for a peculiar breed of goats, which are reared in the vicinity, and produce hair as fine as silk, of which a highly valued woollen cloth is manufactured. The finest kind is reserved for the use of the seraglio of the Grand Signior, and its exportation is prohibited under the penalty of a capital punishment. But 500 or 600 camel-loads of the common sort are annually conveyed to Smyrna, and exported to different countries of Europe. The orchards in the neighbourhood thrive well, and produce pears, which supply the market of Constantinople; and it has some trade in wax and opium, which latter is extracted from poppies cultivated in the surrounding country. The population is stated at 80,000, of which 10,000 are Christians, Greeks, or Armenians, who are chiefly engaged in commercial affairs, and the rest are Turks.

ANGOULEME, a city of France, capital of the former province of Angoumois, and now the chief town of the department of Charente, stands on a rock near the river Charente, contains 16,000 inhabitants, whose chief trade consists in paper, wines, brandy, and salt, and is in N. Lat. 45°. 39′. and E. Long. 0° 14′.

ANGOUMOIS, formerly a province of France, and now constituting the larger proportion of the department of Charente, is bounded on the north by Poitou, and on the south by Perigorde, and produces abundance of corn, wine, and saffron. The brandy, manufactured in large quantities in the vicinity of Cognac, one of the towns of the province, is also a principal source of its trade. In some places iron mines are productive, and a small quantity of antimony has been discovered.

ANGOY, a kingdom on the western coast of Africa, lying between the rivers Cabinda and Zaire, and bounded on the south by Congo. The coast is flat and marshy, but at the distance of a few miles inland the country rises into an elevated region. The inhabitants, although they have some intercourse with the Portuguese and English, who have settlements among them, are still rude, barbarous, and indolent, addicted to idolatry, and indulging in polygamy.

ANGRA, from a word which signifies a *creek*, is the capital of Tercera, one of the Azores, or Western islands, belonging to Portugal, stands on a bay on the south side of the island, is well built, and surrounded with walls, is the see of a bishop, and contains some fine churches, and is a magazine for naval stores to supply the Brazil and East India fleets of the Portuguese. The harbour is safe and commodious in the summer, but in the winter season it is subject to furious tempests. The population is stated at 10,000; and their commercial affairs are limited to the exportation of some corn and a little wine to the Lisbon market. N. Lat. 38° 38′. W. Long. 27° 13′.

ANGUILLA, or Snakes' island, one of the Antilles or Caribbee islands, derives its name from its supposed resemblance to a snake, is about 60 miles north from St Christophers, and is 30 miles long and three miles broad. It belongs to Britain, and was originally settled by the English in 1650. The first settlers were greatly annoyed by French pirates, and afterwards by a party of Irish, who had fled from their native country at the time of the revolution in 1688. The cultivation of the sugar-cane, and the rearing of cattle, are the chief occupations of the inhabitants.

ANGUIS, or Slow-worm, a genus of serpents, which are distinguished from others of this tribe of animals by their sluggish character, which gives origin to the English name. See Ophiology.

ANGURIA, or Water-melon, a genus of plants belonging to the class Monoecia, of which three species have been described. They are cultivated in America and the southern regions of Europe.

ANGUS-SHIRE, a county of Scotland, which is usually described under the name of Forfar-shire. See FORFARSHIRE.

ANHALT, a principality of Upper-Saxony, in the north of Germany, about 60 miles in length and eight in breadth, and lying chiefly between the rivers Elbe and Saal. This district is fertile in grain, and affords a few mineral productions, some of which are the sources of manufactures. The population is estimated at 100,000.

ANHOLT, an island belonging to Denmark, and situated in the Cattegat. The surrounding shoals and sand-banks render the navigation of the seas near this island very dangerous, and have occasioned the erection of a light-house; the exact position of which is in N. Lat. 56° 44′ 20″ and in E. Long. 11° 39′ 51″; ten miles north from Zealand, and eight miles east from the coast of Jutland.

ANJENGO, a small town on the Malabar coast, in the East Indies, which is defended by a fort erected by the English in 1695, is 40 miles north-west from Travancore, and has some trade in long cloths and pepper.

ANIMA MUNDI, or SOUL OF THE WORLD, an imaginary substance among the ancient philosophers, which was supposed to be a pure, ethereal spirit, diffused through the universe, sustaining its various parts, and animating the whole in the same manner as the human soul actuates the body. In some of the ancient systems of philosophy, the soul of the world is considered as a self-existent, intellectual, and eternal principle, the prime mover and active cause of all things in the universe. The human soul was regarded as an emanation from this intellectual principle; and, after death and sufficient purifications, was again restored to its original source. But Plato, who also maintained the doctrine of the soul of the world, ascribed its origin to the Divinity, or great first cause of all things, supposed that the soul which animated the world proceeded from God, and thought that the human soul was derived from it. A doctrine somewhat similar has been revived in modern times under the name of *plastic nature*.

ANIMAL has been defined an organized and living body possessed of sensation. The three great classes of natural objects, minerals, vegetables, and animals, are characterised by Linnæus in the following manner: Minerals grow or increase; vegetables grow and live; and animals grow, live, and have the power of sensation. Later naturalists have divided the objects of nature into two great classes, *organised* or *organic* beings, and *inorganic* bodies. The latter includes minerals; and under the former class vegetables and animals are comprehended. This arrangement furnishes characters sufficiently accurate and precise for the discrimination of minerals, and the two classes of organised beings, vegetables and animals; but the exact definition of vegetables and animals is still wanting. Sensation and loco-motion, ascribed to animals, appear in some degree in certain vegetables; and some animals seem to have the power of sensation and loco-motion in as low a degree as some of the objects of the vegetable kingdom. Mineral bodies are increased by aggregation, by the addition of particles of the same kind of matter as that of which they are composed; but organised bodies are increased by matter of a different kind introduced into tubes or vessels within the vegetable or animal, and by certain processes changed and assimilated to the different parts of the individual. It has been observed by Dumeril, a French naturalist, that the masses in which inorganic bodies present themselves are angular, insulated, and variable in size; that they may be said to be *formed;* and their origin may be traced to attraction. But the individuals called plants and animals have necessarily a form that is constant, for the most part rounded and symmetrical, and their extension is fixed to certain limits; and in increasing their size they only develope themselves. Bodies which increase by aggregation may be divided into very small parts, bearing a near resemblance to the mass from which they are separated; but in plants and animals, which develope themselves, no portion can be taken away and exist by itself, at least unless it develope new parts for the purpose of replacing those that are wanting. But the distinction between vegetables and animals, either from the poverty of language, or the inaccuracy of our knowledge, still remains imperfect; and no definition which assigns the precise limits between those two classes of beings has yet been given.

ANIMAL FLOWER, the trivial name of certain marine animals belonging to the order Mollusca, and class of Vermes, in the Linnæan arrangement. Animal flowers are ranked under three different genera, namely, *Actinia*, *Holothuria*, and *Tubularia*, each of which contains numerous species. The animals of this description are attached by a stem to a particular spot, and in this respect resemble plants; they exhibit somewhat of the form of vegetable flowers, and hence have been denominated *Sea Anemone*, or, from their stinging property, *Sea Nettle*; and they often present the richest and most brilliant variety of colours. See HELMINTHOLOGY.

ANIMALCULE, or little animal, is usually applied to those animals which are invisible to the naked eye, and cannot, therefore, be distinguished and examined without the assistance of microscopes. Animalcules are generally found in water, especially putrid water; and as many of them are developed by the artificial infusions of vegetable and animal matters, they are denominated *Animalcula Infusoria*, or Infusory Animals, by Linnæus, and form the last order of his class of Vermes, under which they may be treated. See HELMINTHOLOGY.

ANIME, a resinous substance, which exudes from the trunk of a large tree, *Hymenæa courbaril*, or locust-tree, a native of Brazil and the West-Indies, is transparent, and of an amber-colour, has an agreeable odour, little or no taste, and dissolves slowly in alcohol and essential oils.

ANJOU, a province of France, part of which is included in the department of Maine and Loire. It is 70 miles long and 60 broad, finely diversified with hills, extensive forests, and fertile plains, watered by numerous streams, and produces grain, fruits, flax, cattle, and sheep.

ANIO, or ANIEN, the ancient name of a river of Italy, now called *il Teverone*, which falls into the Tiber four miles from Rome.

ANISUM, or ANISE, the trivial name of a species of Pimpinella, an umbellated plant, which yields an essential oil.

ANN, or ANNAT, a tax imposed by the see of Rome on all ecclesiastical benefices to which a new incumbent was presented, under the authority of the papal bull. This tax, amounting to a year's revenue, was appropriated to the support of the Sacred College. Sometimes this tax exceeded the amount of the annual revenue of the benefice from which it was levied, and sometimes it was only half that sum. It seems to have varied, according to the influence of the Pope, or his representatives, in different countries.

ANN, or ANNAT, according to the ecclesiastical establishment of Scotland, is half a year's revenue of a benefice to which the heirs or executors of a deceased clergyman are by law entitled. The widow of a clergyman who dies without children has a right to one half of the ann, and his legal heirs to the other. In the case of children, two-thirds fall to them, and one-third to the widow; but if children only survive, the whole belongs to them.

ANNA, one of the chief towns of *Arabia Deserta*, and a great thoroughfare for caravans from Aleppo, Damascus, and Bagdad, stands on the banks of the Euphrates, in an elevated region, which is fertile in corn and fruits, contains about 4000 houses, and is 220 miles south-east from Aleppo, and 260 miles east from Damascus.

ANNABERG, a town of Upper Saxony, is situated in the mountains of Misnia, and not far from the frontiers of Bohemia, owes its origin to the silver mines in the vicinity, and is 38 miles south-west from Dresden, and 14 miles south from Chemnitz.

ANNABON, or ANNOBON, an island on the coast of Loango, in Africa, belonging to the Portuguese, and discovered by them in the 15th century, is in S. Lat. 1° 30′, and E. Long. 5° 40′; yields abundantly all the vegetable productions of tropical climates, is about 30 miles in circumference, and on the north-east side has a convenient roadstead for shipping, with good anchorage.

ANNALS, a species of history, in which the relation of events is arranged in the order of time in which they happened; such, for example, are the *Annals of Tacitus;* and the authors of such works are called annalists.

ANNAMOOKA, or ROTTERDAM, an island in the Pacific ocean. See ANAMOOKA.

ANNAN, a borough town, and the capital of Annandale, a district of Dumfries-shire in Scotland, stands on an elevated bank of a river of the same name, and about a mile distant from its junction with the Solway frith, has many well-built houses, some spacious streets, and a population amounting nearly to 2000, who are employed chiefly in spinning and weaving cotton, in curing pork, and in the exportation of grain, hams, bacon, and hog's-lard to different parts of England. The salmon-fishing, formerly considerable, has greatly declined. Annan is 16 miles distant from Dumfries.

2

ANNANDALE, a district of Dumfries-shire in Scotland, is a fertile valley, traversed by the river Annan, and about 25 miles long and 15 miles broad; from its vicinity to England was subject to predatory incursions, and continued long waste and in a state of commonage, but is now divided, and in many places highly improved, and contains numerous remains of Roman antiquities, as well as many mansions and castles of powerful barons of later times, now in their progress to decay. The great road from London to Edinburgh and Glasgow passes through Annandale.

ANNAPOLIS, the capital of the state of Maryland in North America, stands at the mouth of the river Severn, which was its former name, has a population of 2000, and is distinguished by the state-house, a magnificent edifice, which occupies the centre of the town, and from which the streets branch off in all directions.

ANNAPOLIS ROYAL, assumed this name for Port-Royal in 1713, when it was ceded at the peace of Utrecht by the French to the English, and was thus denominated in honour of Queen Anne, is a small town of Nova Scotia in North America, has some trade in wood, fish, and furs, but is chiefly remarkable for its situation on the south side of a bay which forms one of the most spacious and safest harbours in the world; it is six miles long and three miles broad, and capable of admitting 1000 vessels. The entrance, which is not a mile wide, is difficult, on account of the force of the tides and currents. Annapolis is 80 miles west from Halifax.

ANNEALING, is a process to which glass-ware is subjected to render it less brittle. In the manufacture of all kinds of glass, it is introduced into an oven or furnace, called the annealing or nealing-furnace, the temperature of which is not sufficient to fuse it, and in this furnace it is allowed to cool very slowly. Glass-ware which has not undergone this process, or which has been cooled in the open air, presents some singular properties, which are illustrated by some striking experiments with what are called philosophical phials and glass-tears, or Prince Rupert's drops. The former are made of crystal-glass, are sometimes near an inch thick in the bottom, and may be struck hard on a table or smooth surface without injury. But when an angular bit of flint, a few grains weight, is even cautiously dropped into the inside, they fly to pieces. Prince Rupert's drops are made of common bottle-glass, which is let fall, in a state of fusion, into cold water, and in this way a roundish oblong head, with a long slender tail, is formed. When the least bit of the tail is broken off, while the tear is held in the hand to prevent it from flying about, the whole mass bursts with a smart shock into minute fragments like sand. When they are heated to redness, and allowed to cool slowly in the open air, they acquire the properties of common glass.

When glass passes from the liquid to the solid state by slow cooling, all the parts are uniformly arranged, or are regularly crystallized; and in this state, in consequence of the crystallization, the mass has acquired a greater bulk than in the state of fusion; and then, too, it becomes elastic, and susceptible of long continued vibrations. But the sudden exposure of glass to cold, when passing to the solid state, forms a crust or external covering to the internal parts before they have time to assume a regular arrangement. The internal parts are supposed to be in a state of tension, or compression, from the external crust. When a smart stroke is applied to unannealed glass, as to the philosophical phial, or Prince Rupert's drops, the vibration is instantaneously communicated to the whole mass, and no change is produced; but when the tail of the drop is broken, or the surface of the phial is scratched, the vibration is conveyed along the crystallized surface, and the internal parts are allowed to expand, and thus overcome the cohesion of the outer covering, and burst into pieces. But neither this explanation, nor any other which has yet been offered, is at all satisfactory in accounting for the remarkable difference between annealed and unannealed glass.

Metallic substances exhibit similar differences in their properties. A mass of iron, when hammered, becomes brittle, and requires to be heated to recover its malleable property; and cast-iron vessels, when allowed to cool slowly, acquire considerable elasticity, and are less liable to injury.

ANNECY, or Annici, a town of Savoy, annexed to the department of Mont-Blanc in France, is finely placed on the banks of a beautiful lake of the same name, which is nine miles long and three or four miles broad, is 19 miles south from Geneva, and contains about 5000 inhabitants.

ANNEXATION, in a general sense, denotes the act of uniting one subject to another. In the law of Scotland, this term signifies the union of lands unalienably to the crown. By an act passed in 1455, the annexed royal property was declared to be unalienable without the sanction of parliament; but by subsequent enactments, these precautions were removed, and the property of the crown was completely alienated, with the exception of Edinburgh, Dumbarton, and Stirling castles, and the feu-duties of ancient domains.

ANNEXATION of the *temporality of benefices*, in consequence of the act of the Scottish legislature, includes all church lands which became unalienably the property of the crown, and for the purpose of supporting the royal dignity, with the exception of, 1. Lands previously erected into a temporal lordship; 2. Lands destined to the support of hospitals, and still appropriated to that use; 3. Benefices, the patronage of which, before the Reformation, belonged to laymen; 4. The glebes and manses which belonged to popish churchmen; and, 5. In particular cases, grants of pensions out of benefices.

ANNEXATION, *quoad sacra*, is the union of part of the lands of one parish to another, when such lands are at too great a distance from the parish church. This practice was introduced for the convenience of the inhabitants in attending the ordinances of religion. Annexations of this kind affect only the spiritual concerns of the inhabitants. Their civil connection with the parish from which they were disjoined remains unbroken. The annexed lands are still burdened with the payment of stipend to the clergy of the parish from which they were separated; and they are still liable to be taxed for their former proportion of expense in building and repairing the church and manse of the old parish.

ANNIHILATION is defined the act of reducing a created being to nothing, and has been a fertile subject of speculation among different nations. The Greek philosophers seem to have confined their discussions to the changes and modifications which are constantly observed in the universe, and to have excluded from their consideration every notion of total annihilation. In later times, the possibility or impossibility of such an event has introduced great diversity of opinion among philosophers and divines. Annihilation is regarded by some Christian philosophers as the greatest of all evils; but some eastern nations consider it as the highest degree of felicity, because the soul is delivered from the slavery of continual transmigration. The Persian bramins hold the opinion, that, after certain long periods, the universe, and every created thing which it contains, is to be totally annihilated. But this speculation, like every other in which the terms are not precisely defined, or are imperfectly understood, admits of endless controversy; and perhaps it is beyond the grasp of the human mind.

ANNONA, a genus of plants belonging to the Polyandria class, and including the alligator apple, the custard apple, and the sour and sweet sops of the West Indies.

ANNONAY, a town of Languedoc in France, with a population of between 5000 and 6000, which has been long celebrated for the manufacture of the finest paper in France, or perhaps in Europe.

ANNOTTO, or Arnotto, is a substance which is employed in dyeing a fine red colour, and is obtained from the seeds of a plant, the *Bixa Orellana*, a native of the West Indies and some parts of the American continent. It is sometimes called *Terra Orellana*, and by the French *roucou*, and is in the form of a hard dry paste.

Annotto is prepared by steeping the seeds, separated from the pods, seven or eight days in water, till fermentation commences, and then, by stirring the whole mass, and beating with with wooden stampers to promote the separation of the red skins. The same process is several times repeated, till the whole colouring matter is extracted. The liquor, after being strained, is heated in iron vessels, and throws up a red scum, which is carefully separated, and boiled down to a proper consistence, made up into cakes, wrapped into palm leaves, and in a few weeks is ready for exportation.

Annotto of a superior quality is prepared by the Indians, without the process of steeping or fermentation. The seeds are rubbed between the hands, which have been previously dipped in palm-oil, till the outer coat is separated, and the bright shining paste which remains on the hands is scraped off with a knife, and laid on a clean leaf to dry in the shade.

ANNUALS, or annual plants, are such as spring up, produce seeds, and decay in the same year.

ANNUITIES are periodical incomes, payable from time to time, either annually, half-yearly, quarterly, or at other intervals agreed upon.

The subject of annuities, and topics of a kindred

Annuities.

nature, may date their origin about the middle of the 17th century, when Huygens, and other continental mathematicians, investigated the doctrine of probabilities. The first published discussion on the theory of probabilities is a small treatise by Huygens, entitled, *De Ratiociniis in ludo Aleæ*, which appeared in 1658. This was followed by a small and a little-known work on *Life Annuities*, by the celebrated John De Witt. Dr Halley constructed a table of mortality from observations made at Breslaw, and pointed out how the probabilities of life and death, and the values of annuities and assurances on lives might be deduced from such tables. This memoir appeared in the *Philosophical Transactions* of London for 1693. For the purpose of abridging calculation, M. De Moivre published, in 1724, a treatise on *Annuities on Lives*, in which he assumed the annual decrements on lives to be equal. In 1742, Mr Thomas Simpson elucidated this subject in a more comprehensive manner, and accommodated the formulæ contained in his work on the *Doctrine of Annuities and Reversions* to any tables of mortality. A valuable work, by M. Deparcieux, entitled an *Essay on the Probabilities of Human Life*, appeared in 1764. Dr Price's *Observations on Reversionary Payments*, which was published in 1769, was chiefly intended to fix the principles on which societies might be formed for making provision for the individuals themselves in old age, or for their widows. Mr Morgan's *Doctrine of Annuities and Assurances* appeared in 1779; the 4th edition of Dr Price's work, in 1783, extended the practical application of the principles already established; and *The Principles of the Doctrine of Life-Annuities*, by Baron Maseres, published also in 1783, contributed to throw farther light on the subject. But the latest, and one of the completest works on annuities is *A Treatise on the Valuation of Annuities and Assurances on Lives and Survivorships*, by Mr Milne of the Sun Life Assurance Society, which was published in 1815. Beside the works now noticed, those who are desirous of entering deeply into this investigation, may consult with advantage various Memoirs by Mr Morgan, which are inserted in the *Philosophical Transactions* for 1800, and ten or twelve years preceding.

Annuities are usually divided into such as are in possession, and such as are in reversion; the former being those that have already commenced, and the latter such as will not commence till some particular event has happened, or some given period of time has elapsed.

When an annuity is forborn for some years, or payments not made for that time, the annuity is said to be in arrears.

An annuity may also be for a certain number of years only, and then cease; or it may be without any limit, and may continue for ever, and it is then called a perpetuity.

The sum of all the annuities, for the time they have been forborn, together with the interest upon each after it becomes due, is called the amount.

The present worth or value of an annuity, is the price or sum which ought to be given for it, supposing it to be bought off, or paid all at once.

Calculations of annuities are usually made at compound interest, by means of convenient tables constructed for that purpose, and to calculate any sum without them is nothing more than to show how these tables are formed.

The first thing to be done is to find the amount of L.1, at any rate per cent. compound interest, and then multiply this by the sum of which we propose to find the amount; and first, at 5 per cent. to find the amount of L.1 for any number of years, we have only to state thus; by the rule of proportion, if L.100 amount to L.105, what will L.1 amount to; the answer is, fractionally, $\frac{105}{100}=\frac{21}{20}$, amount for the first year;

$20:21::\frac{21}{20}:\frac{21}{20}\times\frac{21}{20}=\left.\frac{21}{20}\right)2$, amount at the end of the second year;

$20:21::\left.\frac{21}{20}\right)2:\left.\frac{21}{20}\right)2\times\frac{21}{20}=\left.\frac{21}{20}\right)3$, amount at the end of the third year.

In the same manner it appears, that this last amount, improved at interest, in the same way, during the fourth year, will be increased to $\left.\frac{21}{20}\right)4$: at the end of the fifth year it will be $\left.\frac{21}{20}\right)5$; and so on; the amount at the end of any number of years being always determined by applying to the amount at end of the first year, an index or exponent equal to the number of years.

If the rate of interest were 4 per cent. the amount for five years would be represented by $\left.\frac{26}{25}\right)5$; and at 3 per cent. by $\left.\frac{103}{100}\right)5$; respectively.

Ex. 1. Required the amount of L.50 for five years, at 5 per cent. compound interest:

This would be $\left.\frac{21}{20}\right)5\times 50$, and $\left.\frac{21}{20}\right)5 = 1.27628$ = the amount of L.1, and this multiplied by L.50, or $\left.\frac{21}{20}\right)5\times 50=1.27628\times 50=63.814=$ L.63, 16s. $3\frac{1}{4}$d. the amount required.

Ex. 2. Required the amount of L.750, for fifty years, at $4\frac{1}{2}$ per cent.

$100:104.5$, or $\left.\frac{104.5}{100}=\frac{20.9}{20}\right)50\times 750=6774.4725$ = L.6774, 9s. $5\frac{1}{4}$d.

Ex. 3. Required the amount of L.150 for ninety-one years, at 5 per cent.

$\left.\frac{21}{20}\right)91\times 150=12715.0325=$ L.12715, 0s. $7\frac{1}{2}$d.

Ex. 4. Required the amount of L.365, for twenty-five years, at 4 per cent.

$100:104$, or $\left.\frac{26}{25}\right)25\times 365=973.032=$ L.973, 0s. $7\frac{1}{2}$d.

Annuities.

A Table might be constructed to facilitate these operations at different rates per cent.

	Years	2 Pr. Cent.	3 Pr. Cent.	4 Pr. Cent.	5 Pr. Cent.	6 Pr. Cent.
At 2 per cent. $\frac{51}{50}$	1	1.020	...	...	...	...
— 3 do. $\frac{103}{100}$	...	...	1.030	...	...	...
— 4 do. $\frac{26}{25}$	...	...	...	1.0400	...	...
— 5 do. $\frac{21}{20}$	...	...	...	...	1.0500	...
— 6 do. $\frac{53}{59}$	..	...	..	...	. .	1.0600
The same at 2 years would be as follows :						
At 2 per cent. $\left.\frac{51}{50}\right)^2$	2	1.0404	..	...	..	..
— 3 do. $\left.\frac{103}{100}\right)^2$	...	...	1.0609	...	...	..

3 p. cent. 3 p. cent. 4 p. cent. 5 p. cent. 6 p. cent.						
$\frac{51}{50}$ $\frac{103}{100}$ $\frac{26}{25}$ $\frac{21}{20}$ $\frac{53}{50}$	1	1.0200	1.0300	1.0400	1. 050	1.0600
$\left.\frac{51}{50}\right)^2$ $\left.\frac{103}{100}\right)^2$ $\left.\frac{26}{25}\right)^2$ $\left.\frac{21}{20}\right)^2$ $\left.\frac{53}{50}\right)^2$	2	1.0404	1.0609	1.0816	1.1025	1.1236
$\left.\frac{51}{50}\right)^3$ $\left.\frac{103}{100}\right)^3$ $\left.\frac{26}{25}\right)^3$ $\left.\frac{21}{20}\right)^3$ $\left.\frac{53}{50}\right)^3$	3	1.0612	1.0927	1.1248	1.1762	1.19102
$\left.\frac{51}{50}\right)^4$ $\left.\frac{103}{100}\right)^4$ $\left.\frac{26}{25}\right)^4$ $\left.\frac{21}{20}\right)^4$ $\left.\frac{53}{50}\right)^4$	4	1.0824	1.1255	1.1698	1.2155	1.2625

The amount of L.1 annuity may be found nearly in the same manner.—For,

1 year's amount, at 5 per cent. is 1. 1.00000

2 do. do. is $1+\frac{21}{20}=\frac{21^2}{20}-20$ 2.05000

3 do. do. is $1+\frac{21}{20}+\left.\frac{21}{20}\right)^2=\frac{21^3}{20^2}-20$ 3.15250

4 do. do. is $1+\frac{21}{20}+\left.\frac{21}{20}\right)^2+\left.\frac{21}{20}\right)^3=\frac{21^4}{20^3}-20$ 4.310125

5 is $1+\frac{21}{20}+\left.\frac{21}{20}\right)^2+\left.\frac{21}{20}\right)^3+\left.\frac{21}{20}\right)^4=\frac{21^5}{20^4}-20$ 5.525631

These quantities may be calculated separately, but much better by summing this geometrical progression of which the first term is 1, and common ratio $\frac{21}{20}$, then taking for example the fifth of these, multiply the last term by the ratio, and from the product subtract the first term and divide by the ratio minus 1, that is,

$$\frac{\left.\frac{21}{20}\right)^4\times\frac{21}{20}-1}{\frac{21}{20}-1}=\frac{\left.\frac{21}{20}\right)^5-1}{\frac{21-20}{20}}=\frac{21^5}{20^4}-20\text{..............}5.525631$$

This is the amount of L.1 annuity for five years, at 5 per cent. and the amount of any other sum, at the same rate and time, may be found by multiplying this by the sum proposed. *Ex.* 1. L.100, which must be 100 times this, would amount to $\left(\frac{21^5}{20^4}-20\right)\times 100=5.525631\times 100=552.563=$L532 11s. 3d. nearly.

Ex. 2.--The amount at 2 p. ct. for same time would be

$$1+\frac{51}{50}+\left.\frac{51}{50}\right)^2+\left.\frac{51}{50}\right)^3+\left.\frac{51}{50}\right)^4=\frac{\left.\frac{51}{50}\right)^5-1}{\frac{51}{50}-1}=\left(\frac{51^5}{50^4}-50\right)\times 100=5.20404\times 100=520.404=\text{L.}520,\ 8\text{s. }1\text{d.}$$

nearly.

Ex. 3. Required the amount of an annuity of L.50, in 20 years, at $3\frac{1}{2}$ per cent. compound interest.

100:103.5, or $\frac{20.7}{20}$, then $\frac{20.7}{20}$ is the ratio, and

$$\frac{\frac{20.7^{20}}{20^{19}}-20}{.7}\times 50=28.2797\times 50=1413.985=\text{L}1413\ 19\text{s. }8\tfrac{1}{4}\text{d.}$$

Ex. 4.—Required the amount of an annuity of L.80, in 30 years, at 4 per cent. compound interest.

100:104, or $\frac{26}{25}$ is the ratio, then $\left(\frac{26^{30}}{25^{29}}-25\right)\times 80=$ $56.0849377\times 80=4486.795=$L.4486, 15s. 10¼d.

Ex. 5.—Required the amount of an annuity of L.40 in 18 years, at 4 per cent. compound interest, then $\left(\frac{26^{18}}{25^{17}}-25\right)\times 40=25.6454\times 40=1025.826=$ L.1025 16s. 3¾d.

The present value of any sum of money may be calculated for any number of years, at any rate per cent. in a similar manner; that is, any sum which is payable only after a certain number of years.

As L.20 in ready money, at 5 per cent. amount to L.21 in twelve months, so reciprocally, L.21, which cannot be received till the end of one year, are really worth only L. 20. *Example* 1.—Required the present value of L.50, the payment of which is due at the end of one year, it must be multiplied by $\frac{20}{21}$, or $\frac{20}{21}\times 50$, and $\frac{20}{21}=.95238$, then $\frac{20}{21}\times 50=$ $.95238\times 50=47.619.=$L.47, 12s. 4½d. and at the end of 3 years it would be $\frac{20}{21}3\times 50=863838\times 50=$L.43 3s. 10d.

*Ex.*2.—Required the present value of L.246, due at the end of 30 years, at 5 per cent. compound interest. This will be $\left.\frac{20}{21}\right)^{30}\times 246=56.9180=$L.56, 18s. 4½d.

*Ex.*3.—Required the present value of L.239, due at the end of 37 years, at 5 per cent. compound interest: Then $\left.\frac{20}{21}\right)^{37}\times 239=39.3002=$ L.39, 6s.

A table constructed for facilitating these calculations would begin thus: 105:100 or 21:20::1: $\frac{20\times 1}{21}=\frac{20}{21}$, so that the present value of L.1, at the end

of 1 year is $\frac{20}{21}$........ .95238

2 do. $\left.\frac{21}{20}\right)^2$........ .90703

3 do. $\left.\frac{20}{21}\right)^3$........ .86384

&c.

the exponent of this fraction being always the same as the number of years.

At 4 per cent. it will be } 104:100: or 26:25::1:$\frac{25\times 1}{26}=\frac{25}{26}$

For one year is $\frac{25}{26}$........ .961538

2 do. - $\left.\frac{25}{26}\right)^2$........ .924556

3 do. - $\left.\frac{25}{26}\right)^3$........ .888996

&c.

The present value of an annuity is that sum which, when improved at compound interest, would be sufficient to pay the annuity; and the present value of the whole annuity is the sum of the present value of its several payments. When a certain sum of money is received annually, it is called an annuity of so much; if the annual payment be L.1, L.100, or L.300, it is called an annuity of L.1, of L.100, or of L.300.

Now the present value of L.1 annuity, at 5 per cent. for example, and then that sum multiplied into the sum proposed, will produce the present value of that sum.

The present value of L.1 would be } 105:100 or 21:20::1:$\frac{20\times 1}{21}=\frac{20}{21}$

For 1 year it is $\frac{20}{21}$........ .95238

2 do. $\frac{20}{21}+\left.\frac{20}{21}\right)^2=20-\frac{20^3}{21^2}$........ 1.85941

3 do. $\frac{20}{21}+\left.\frac{20}{21}\right)^2+\left.\frac{20}{21}\right)^3=20-\frac{20^4}{21^3}$..... 2.72325

4 do. $\frac{20}{21}+\left.\frac{20}{21}\right)^2+\left.\frac{20}{21}\right)^3+\frac{30^4}{21}=20-\frac{26^5}{21^4}$ .. 3.5459

5 do. $\frac{20}{21}+\left.\frac{20}{21}\right)^2+\left.\frac{20}{21}\right)^3+\left.\frac{20}{21}\right)^4+\left.\frac{20}{21}\right)^5=20-\frac{20^6}{21^5}$ ..

&c. [4.32947

Ex. 1.—Required the present value of an annuity of L.60, for 5 years, at 5 per cent. compound interest, it would be $\left(20-\frac{20^6}{21^5}\right)\times 60=4.32947\times 60=259.7682$ $=$L.259, 15s. 4¼d. And at 4 per cent. the present value of the same sum, for the same number of years, would be, $25-\frac{25^6}{26^5}\times 60=4.4518\times 60=267.1080=$ L.267, 2s. 1¾d.

Ex. 2.—Required the present value of an annuity of L.50, which is to continue 20 years, at 3½ per cent. 103.5 : 100, or $\frac{100}{103.5}=\frac{20}{20.7}=$ the ratio, and also the first term.

$\dfrac{\left(20-\frac{20^{21}}{20.7^{20}}\right)}{.7}\times 50=710.62=$L.710, 12s. 4½d.

Ex. 3.—Required the present value of an annuity of L.30, for 7 years, at 6 per cent.

106:100, or $\frac{50}{53}$ is the ratio, and likewise the first term. Then $\left(50-\frac{50^8}{53^7}\right)\times 30=5.5823815\times 30=167.471445$ $=$L.167, 9s. 5d.

Ex. 4.—Required the present value of an annuity of L.20, to commence ten years hence, and then to continue for 11 years longer, or to terminate 21 years hence, at 4 per cent. Here we must find the difference between the present values of two equal annuities, for the two given times, which is done by substracting the value of the one period from that of the other, and multiplying this difference by the given annuity.

At 4 per cent. the ratio and first term is $\frac{25}{26}$.

Then $\left(25-\frac{25^{22}}{26^{21}}\right)\times 20=$value of one period,

and $\left(25-\frac{25^{11}}{26^{10}}\right)\times 20=$ value of the other;

their difference is $\left(25-\frac{25^{22}}{26^{21}}-25+\frac{25^{11}}{26^{10}}\right)\times 20=$ $\left(\frac{25^{11}}{26^{10}}-\frac{25^{22}}{26^{21}}\right)\times 20=5.9188\times 20=118.366=$L.118, 7s. 3½d. Ans.

Annuities.

Each of these sums forms a geometrical progression, of which the first term and common ratio are the same, being $\frac{20}{21}$: and the sum of the progression is found, as usual, by multiplying the last term by the common ratio, and subtracting the first term; and dividing this by the ratio, minus 1, gives the sum of the series. Now the sum of all these, if extended to infinity, would give the perpetuity; but the powers of this fraction, $\frac{20}{21}$ continually go on decreasing in value, for $\frac{20}{21}=\frac{1}{1.05}$, of which the powers of the numerator are always the same, and those of the denominator continually increasing, evidently decreases the value of the fraction, till at length it may be considered as nothing, when 20 will then remain for the value of the perpetuity.

If the rate per cent. be L. 3, the formula for this will then be $103 : 100 :: 1 : \frac{100\times 1}{103}=\frac{100}{103}$; then $\frac{100}{103}+\frac{100}{103}\Big)2$, for two years, and the sum will be

$$\frac{\frac{100}{103}\Big)3-\frac{100}{103}}{\frac{100}{103}-1}=33\tfrac{1}{3}-\tfrac{1}{3}\times\frac{100^3}{103^2}$$

: where the perpetuity is $33\frac{1}{3}$.

It appears therefore, in every case, that whatever be the rate per cent. the first part of this general formula will always represent the perpetuity.

The amounts of sums of money are often calculated for half-years, and annuities very commonly paid in half-yearly payments, and sometimes quarterly; but the same method of calculation will equally answer this purpose. For if we want to know the amount of L.100 in 20 years, for example, when the interest is at 4 per cent. and convertible into principal half-yearly; considering that 20 years is equivalent to 40 half-years at 2 per cent. interest for every half-year, it will be the same as the amount in 40 years at 2 per cent.; this would be $\frac{51}{50}\Big)40\times 100=2.20804\times 100=220.804=$ L.220, 16s. 1d. the required amount, and is more than it would have been if reckoned yearly by L.1, 13s. 10d.

If an annuity is to be paid half-yearly, it is plain the one-half must be paid after one half-year, and the other half of it at the end of the next; we must therefore multiply the present value of L.1 for twice the number of years given, by half the given annuity. If it were required to find the present value of an annuity of L.50 for 21 years, to be received in half-yearly payments, interest being at 5 per cent. per annum, or at $2\frac{1}{2}$ per cent. every half-year, this appears as follows:

$102.5 : 100$: or $\frac{100}{120.5}=\frac{4}{4.1}$, then $4-\frac{4^{43}}{4.1^{42}}\times 25=25.8206\times 25=645.515=$ L.645, 10s. $3\frac{1}{4}$d., the value required; and exceeds the value when interest and annuity are payable only once a-year by about L.4, 9s. 1d.

These four principles, from which four corresponding tables may be constructed, being brought into one view, if we take, for instance, the term of three years, and the rate of interest 5 per cent. will appear thus:

1st, Amount of L.1, at compound interest for 3 years, $\frac{21}{20}\Big)3$ 1.15763

2d, Amount of L.1, annuity com. interest for 3 years, $1+\frac{21}{20}+\frac{21}{20}\Big)2=\frac{21^3}{20^2}-20$ 3.15250

3d, Present value, of L.1 compound interest to be received at the end of 3 years, $\frac{20}{21}\Big)3$ .... .86384

4th, Present val. of 1*l.* annuity com. interest for 3 years, $\frac{20}{21}+\frac{20}{21}\Big)2+\frac{20}{21}\Big)3=20-\frac{20^4}{21^3}$ 2.72325

These four formulas having all nearly the same *form*, may be retained in the memory with the greatest facility, and the most useful calculations may be readily performed without any reference to tables, which may not always be ready at hand.

From the first and third forms, the results are evidently obtained by raising $\frac{21}{20}$, and $\frac{20}{21}$, to the power represented by the number of years; and, from the second and fourth, the results are obtained by summing as many terms of the two geometrical progressions respectively, as are the same as the number of years proposed.

All these operations become very easy, by using the logarithms.

ANNUITIES, *borrowing upon*, a method employed by government for raising supplies. According to this system, money is raised by borrowing either upon annuities for terms of years, or upon annuities for lives. An annuity for a long term of years, although nearly equal in intrinsic value to a perpetual annuity, meets with fewer purchasers; for as the subscribers to a new loan generally mean to sell their subscription as soon as possible, a perpetual annuity, redeemable by Parliament, is preferred to an irredeemable annuity for a long term of years of equal amount. The former, as its value continues always nearly the same, is a more convenient transferable stock than the latter. Annuities, either for terms of years or for lives, are sometimes granted as a premium to the subscribers to a new loan, in addition to the redeemable annuity or interest, upon the credit of which the loan is supposed to be contracted for, and then they are considered only as an encouragement to the lender.

Annuities for lives are also granted, either upon separate or joint lives. Such annuities are denominated *Tontines*, from the inventor's name. When they are granted upon separate lives, the death of every annuitant relieves the public revenue from his annuity. But when annuities are granted upon Tontines, the liberation of the public revenue does not commence till the death of all the annuitants included in the scheme; and the last survivor succeeds to the whole. Upon the same revenue more money can be raised by Tontines than by annuities for separate lives; for an annuity, with a right of survivorship, is really worth more than an annuity of equal amount for a separate life; and, from the natural confidence of every man in his own good fortune, such annuities generally sell for something more than they are worth; and on this account Tontines are preferred to annuities for separate lives, in countries where this mode of raising supplies is adopted.

ANODYNE, from a Greek word which signifies *without pain,* is the name applied to such medicines as remove or alleviate pain. Of medicines which possess this property, opium, or some of its preparations, are the most certain, and at the same time the most powerful in their effects. See MATERIA MEDICA.

ANOMALISTICAL YEAR, is the period of the earth's revolution from one point of its orbit to another. It is sometimes also called the *periodical* year. On account of the precession of the equinoxes, the period of this year is greater than the tropical year.

ANOMALY, from a Greek word signifying *unequal,* is any irregularity in the motion of the planets, or the angular distance of the sun and moon from their apogee, or of the primary planets from their aphelion.

ANOMIA, a genus of bivalve shells, one of the characters of which is a perforation near the hinge of the lower valve. The fossil species of anomia are not unfrequent in chalk and limestone in Britain. See CONCHOLOGY.

ANOREXIA, or ANOREXY, from the Greek, and signifying *want of appetite,* a disease in which the natural desire for food is diminished, or which is increased to a loathing of food, is to be considered either as an original affection of the digestive organs, or a symptom of some other disorder.

ANOSSI, a province of the island Madagascar. See MADAGASCAR.

ANQUETIL DU PERRON, ABRAHAM HYACINTH, a distinguished Oriental scholar, was born at Paris in December 1735, was admitted, at a proper age, a student in the university of his native city, and soon became familiar with the different dialects of the Hebrew tongue. By the advice of friends, rather than by his own inclination, he commenced the study of divinity; but the bias of his mind still led him to enlarge his knowledge of the Hebrew, Persian, and kindred languages. His frequent visits to the royal library at Paris, in the prosecution of his favourite studies, attracted the notice of some learned men, through whose influence he obtained a small share of royal patronage, in the benefit of a salary as a student of Oriental literature; and about the same time the discovery of some manuscripts in the *Zend*, or Sacred Book, which contains the religious code of the Persians, induced him to form the romantic plan of a voyage to India, for the purpose of collecting the works of Zoroaster, the great Persian legislator; and although the application of his friends was unsuccessful in procuring for him an appointment in an expedition destined for India, which was then in preparation, he was not to be diverted from his resolution; he enlisted as a common soldier, and, with a knapsack on his back, had actually marched from Paris to join the troops which were to sail in the fleet, when, by a second interference of friends who could appreciate and admire the inextinguishable ardour of his mind, a free passage to India was obtained, and a suitable salary for his support was appointed. He arrived at Pondicherry in August 1755; with his usual perseverance soon became master of the modern Persian; and in the hope of acquiring a knowledge of the Sanscrit, he visited Chandernagore. Disappointed of the last object, and after a tedious journey full of perils and adventures, he returned to Pondicherry, and soon after proceeded to Surat, where he enjoyed frequent intercourse with the native priests, and greatly improved his knowledge of the eastern languages.

The war between France and Britain deranged his future plans; and the capture of Pondicherry precluding all hope of a residence at Benares, which he contemplated for the purpose of studying the languages, sacred laws, and antiquities of the Hindoos, he returned to Europe in an English ship, landed at Portsmouth, and having visited London and Oxford, reached his native city in 1762, after an absence of seven years.

Destitute of worldly fortune, but rich in the spoils of Oriental literature, M. Anquetil resumed his station in the royal library, was appointed interpreter of eastern languages, and commenced his labours in arranging the materials which he had collected for publication. His large work, *Zend-Avesta*, or Sacred Writings of the Persians, appeared in 1771, in 3 vols. 4to, and is considered by competent judges a valuable accession to Indian literature. He published various other voluminous works, chiefly connected with the languages, manners, and establishments of eastern countries; and having escaped the storms of the revolution, during which he secluded himself from society, and was entirely occupied in literary labours, he terminated a life of 74 years at Paris in 1805. The ardent zeal, indefatigable industry, and profound research, displayed in a long career of study, throw a bright lustre on his character; but it was obscured by excessive vanity, an unamiable temper, and no small degree of national prejudice.

ANSER, the specific name of the common goose. See ANAS, under ORNITHOLOGY.

ANSERES, one of the orders of birds in the Linnæan classification. See ORNITHOLOGY.

ANSIKO, or ANZIKO, a kingdom of Africa, which is bounded on the north by some of the deserts of Nubia, and on the south by part of Congo. The inhabitants, according to the scanty accounts which Europeans have received of them, are in a state of extreme barbarity, and it is said, but it surely exceeds belief, that they are such cannibals as to have a public market for human flesh; but, without inquiring into the truth of this assertion, it may be well doubted whether a people in a state of such rudeness have any market at all.

ANSON, GEORGE, LORD, a British admiral and circumnavigator, was a native of Staffordshire in England, and was born in 1697; entered early into the naval service, and in his 25th year was appointed to the command of a sloop of war. Promoted soon after to the rank of post-captain, he performed several voyages to North Carolina during the succeeding ten or twelve years, and in this service acquired considerable wealth.

But the arduous voyage in which he circumnavigated the globe forms the most memorable incident of his life. With five ships of the line, and some attendant vessels of a smaller description, placed under his command, he sailed from England in September 1740, for the purpose of attacking the Spanish settlements on the western coasts of America, while Admiral Vernon was occupied on a similar service on the opposite shores of Mexico. In doubling Cape Horn he encountered the most tempestuous weather; a severe gale of forty days duration dispersed his squadron; and the scurvy made dreadful ravages among his men. Having repaired his fleet at Juan Fernandez, he sailed to Peru, and destroyed the town of Paita on that coast; but his diminished numbers and sickly crews prevented any farther attempt in the prosecution of hostilities on land, and induced him to proceed westward across the Pacific ocean in the hope of intercepting the Spanish treasure ship, which passes annually between the Philippine isles and Acapulco. On this passage, the Gloucester, the only remaining ship of his squadron, beside his own, became leaky, and was abandoned; and the united crews, enfeebled by sickness, could scarcely conduct the Centurion to the Ladrone islands. They landed on Tinian to water and refresh; and while the commander and great part of the crew were on shore, a storm arose in which the ship slipped her anchors, and was driven out to the wide ocean. Eighteen days of anxious suspense passed over their heads before the Centurion appeared; and during that period, while their bosoms were agitated with the varying emotions of hope and despair, they had actually commenced the equipment of a small vessel found on the island. With a crew renovated in health and vigour, Captain Anson sailed to Macao in China; on his return he had the good fortune to capture a rish Spanish galleon; and with this prize of immense value, he proceeded to Europe by the Cape of Good Hope, and arrived in England in June 1744, after nearly four years absence. Soon after his arrival he was promoted to the rank of admiral, and appointed a commissioner of the admiralty.

In 1747, while in command of the Channel fleet, the successful capture of six French ships of the line and four East Indiamen, made a large accession to his riches and honours. He was immediately raised to the rank of nobility; in a few years was placed at the head of the naval administration; and at last obtained the chief command of the British fleet. He died in June 1762.

Lord Anson was remarkable for taciturnity and equanimity of mind. Under his authority the discipline of the navy was improved; and the revival of the close mode of fighting, which he accomplished, gave full scope to the undaunted bravery and invincible courage of British seamen. The eventful narrative of his voyage round the world, published under the name of Mr Walter, chaplain of the Centurion, was drawn up from Lord Anson's journal by Mr Benjamin Robins, whose curious experiments and ingenious researches in physical science have raised him to a high degree of celebrity as a natural philosopher; and those readers only who have not perused it need be informed, that the English language can boast of few works of deeper interest.

ANSPACH, a marquisate of Franconia in Germany, is bounded by the territories of Nuremberg, Wurtzburg, and Bayreuth, is about 50 miles long, and presents a mountainous aspect. The soil is light and sandy, but produces grain, pulse, and some tobacco. The vine thrives on the banks of the Mayne, and yields an excellent wine; and the rich meadows afford abundant pasture to a fine breed of cattle. Iron and varieties of marbles are enumerated among the mineral productions; and the inhabitants, who exceed 215,000, beside agricultural affairs, are occupied in the manufacture of woollen cloths, tapestry, hats, silk stockings, porcelain, glass, gold and silver lace, and needles. This territory was assigned to the king of Prussia in 1791, during the revolutionary distribution of the French, formed part of one of the new German kingdoms, and has now probably returned to the sovereignty of its former master.

Anspach is the capital of the marquisate of the same name, is about twelve miles distant from Nuremberg, and is chiefly known as the seat of a porcelain manufactory which was established about the beginning of the 18th century.

ANT, the trivial name of different insects which are arranged under different genera; as the common ant, which comes under the genus *formica*; the lion ant, which belongs to *myrmeleon*; and the white ant, a species of *termes*. See Entomology.

ANTA, or Anten, a small mountainous district on the Gold Coast of Africa, which is about 30 miles in length, and has been dignified with the name of kingdom; but the fertile vallies afford rich fruits, some grain, and abundance of goats and poultry. Canoes 30 feet long, and seven or eight feet broad, formed of a single tree, are made in this province, are capable of admitting a cargo of 10 or 12 tons, and are reckoned superior to any other in Guinea.

ANTAB, or Antiochette, a town of Syria, which occupies two hills and the intermediate valley, is about three miles in circumference, and is watered by a stream, part of which is conveyed by aquæducts to the upper parts of the town. The dwelling houses are erected on the hills, and the shops in the vallies have terraced roofs, through the openings of which, for admitting light, a stranger is struck with the singularity of a crowded street under his feet. Bows and saddles which are in much repute, and a coarse kind of printed calicoes, are the chief manufactures and sources of commercial activity. Antab is 40 miles north from Aleppo.

ANTÆOPOLIS, the ancient metropolis of the Thebaid in Egypt, now reduced to a poor village, which exhibits a sad contrast with the portico of a temple, the only remains of a magnificent structure dedicated to Antæus. A stone which forms part of the covering of the portico is thirty feet long and five feet broad; but the gold and azure colours of the cieling, as they are described by travellers, retain all their original brilliancy.

ANTÆUS, according to ancient mythology, was

Antarctic || Antediluvians.

a giant of Libya, and the son of Neptune and Terra, and was celebrated for his vast strength and his skill in wrestling. Having formed a resolution of erecting a temple to his father with human skulls, he slew all that he met to supply himself with materials. Hercules at last became his antagonist, and perceiving that he derived new vigour from his mother earth every time that he touched the ground, raised him into the air, and squeezed him to death.

Antæus and Atlas are supposed to refer to the same person, from the similarity of the incidents of their lives. They were both sons of Neptune; they were both kings of Mauritania; both were famed for their knowledge of astronomy; both invaded Egypt; and both were vanquished and slain by Hercules.

According to the explanation of Sir Isaac Newton, Ammon, the father of Sesac, was the first king of Libya, or that extensive region which stretches from the confines of Egypt to the Atlantic ocean, the conquest of which was accomplished by Sesac, during his father's reign, about a thousand years before the Christian era. After the death of Ammon, the Libyans were excited to rebellion through the influence of Neptune; Sesac was slain, and an army under the command of Antæus or Atlas was sent to invade Egypt. But Hercules, the general of Thebais and Ethiopia, vanquished and slew Antæus, and thus a second time reduced the whole of Libya. Antæus fell near the spot where the city which received his name was built.

ANTARCTIC signifies what is opposite to the arctic, or north pole, as, the *antarctic* pole, the *antarctic* circle, the *antarctic* regions, referring to the south pole and southern regions.

ANTEDILUVIANS, the human race who lived before the flood. Their history which, according to the most approved computation, embraces the long period of 1656 years, is narrated by Moses within the narrow compass of seven chapters in the beginning of Genesis. While a more detailed account was unnecessary for accomplishing the object he had in view, this is the only authentic information that can be obtained; and inquiry cannot proceed beyond these limits without indulging in doubtful speculation. Following the narrative of the sacred historian, we shall state the facts which he records, with such observations and comments as they may suggest.

Adam and Eve.—In adverting to the primitive inhabitants of the earth, our two great progenitors present the first claim to our attention. On the sixth day from the commencement of the creation, when this terrestrial globe was fitted up as an agreeable residence for man, Adam and Eve were brought into existence, as actors on the mighty stage, and admirers of its rich and magnificent scenery. Unlike their descendants, who enter life in a state of infancy and weakness, they sprang from the hands of their Maker in the fullest corporeal and mental perfection; their bodies possessing all that is exquisite in beauty, proportion, and strength; and their minds all that is vigorous in intellect, noble in sentiment, holy in desire, or pious in feeling. This was the Golden Age alluded to by the writers of classic antiquity, when fidelity and virtue were spontaneously cultivated when the Supreme Judge was sincerely worshipped, and when guilt and wretchedness were unknown.

Yet, high as they stood in perfection, Adam and Eve were still mutable; and in an evil hour, by listening to the suggestions of the deceiver, they disobeyed the divine command, and forfeited their honour and their happiness. Fear and remorse now agitated their breasts, the heavens lowered upon them in darkness, and the fair creation of God denied them its smiles.

> Earth felt the wound, and nature from her seat
> Sighing through all her works, gave signs of woe,
> That all was lost.

Amid their consternation and distress, which, but for some gleam of consolation, would have proved insupportable, the offended Creator made known to them his merciful intentions, in declaring that *the seed of the woman should bruise the head of the serpent*, by whom they had been betrayed into rebellion, and plunged into misery. Having interrogated them on the crime they had committed, and, in anticipation, held out to them the dawn of a brighter day upon the world, he clothed them with *coats of skins*, instead of the *fig-leaves* with which they had been formerly covered; expelled them from the Garden of Eden, where they had enjoyed whatever could gratify the senses, please the imagination, or elevate the soul, and doomed them to drag out a life of anxiety, toil, and pain, until death should reduce them to their original dust. In this melancholy event we recognise the Silver Age of the poets, when the corruption of the human heart began to be displayed.

Different opinions have been entertained respecting the interval between the formation of our primeval parents and their apostacy from God. According to one opinion, they lost their innocency and were banished from paradise in the evening of the very day on which they were made; according to another they fell on the *eighth* day of the world, it being supposed probable that, as the *first* week terminated with their creation, the *second* would terminate with their departure from righteousness. A third opinion is, that they revolted on the *tenth* day, since, in remembrance of that catastrophe, the great day of atonement was observed on the tenth of Tisri, the month with which the Jewish civil year commenced; and a fourth is, that they maintained their rectitude *forty* days, as many of the principal trials recorded in scripture, and especially the temptation of Christ, of whom Adam was a type, lasted a similar period. The first of these opinions, which was adopted by most of the Jews and some of the Christian fathers, is by no means probable, because it crowds too many incidents into a short space, and allows not time sufficient for the multifarious transactions in which they were engaged previously to their violation of the covenant. But which of the other three, or whether any of them be founded in truth, it is impossible to determine, for want of proper data on which to proceed in drawing a conclusion.

Cain and Abel.—Soon after the expulsion of Adam and Eve from the garden, their first son, Cain, whose name denotes *possession*, was born. Looking on him, it should seem, as the promised seed who should vanquish the devil, and repair the ruin he had occasioned, Eve exclaimed in a transport of joy at his birth, "I have gotten a man from the Lord;" or, as it might otherwise be rendered, "I have acquired a man, even Jehovah." No such expectation was formed, or exultation expressed, when she brought forth her next son, whom she called Abel, to signify something *vain*, or transient, probably because she now felt her hopes disappointed with regard to the Messiah's immediate appearance; or, because she was now taught, by bitter experience, that all earthly enjoyments were "vanity and vexation of spirit." The former of these sons was "a tiller of the ground," and the latter a keeper of sheep; and if their employments were different, so also were their dispositions of mind. Cain was fierce, cruel, and dissembling; Abel was gentle, harmless, and open. Cain was abandoned to iniquity; Abel was religious and upright. An event at length occurred which stamped infamy on the character of the one, while it shed a glorious lustre on the character of the other. Each of them, at the time and place appointed, presented his offering to the Lord, but Cain's was refused and Abel's accepted. From that moment sentiments of jealousy began to operate in the bosom of Cain, and, cherishing the most deadly intention against his brother, he proposed to him a walk in the fields, that, removed from human eye, he might the more easily accomplish his sanguinary purpose. Abel, who, on the other hand, beheld him with the tenderest fraternal affection, suspecting no evil, readily complied, and fell a victim to his maddening fury. This fixes the era of the Brazen Age, when men, though as yet not wholly corrupted, became savage in their tempers, and prone to deeds of violence and oppression.

> ——————— *aënea proles*
> *Sævior ingeniis et ad horrida promptior arma,*
> *Nec scelerata tamen.* Ovid.

With the Mosaic account of Cain and Abel, heathen tradition remarkably coincides. Sanchoniatho, in his Phœnician history, tells us that the immediate descendants of the two first mortals, Protogonus and Eon, were *Genus* and *Genea*, a male and a female; and Bishop Cumberland, in his Annotations accompanying his translation of the fragments of that history handed down to us by Eusebius, infers, from various circumstances, that Genus and Genea were Cain and his sister. In the Hindoo mythology the first Menu, surnamed Swayambhuva, or son of the Self-existent, had by his wife Satarupa, besides three daughters, two *sons*, who were particularly distinguished, and, from what is said of the Deity descending from heaven to be present at their offering, it would appear that this distinction was such as marked the respective characters of Cain and Abel. And among the Iroquois Americans it has been believed from time immemorial, that the first woman, after she was seduced from her obedience to God, and, in consequence, driven from Paradise, bore two sons, the one of whom was attacked and slain by the other.

Sign given to Cain.—On the murder of his brother Abel, and the denouncement against him for that nefarious transaction, Cain felt all the horrors of sullen despondency, and exhibited a melancholy picture of misery and impenitence. No relentings seem to have taken place in his soul; the only considerations which extorted a complaint from his hardened breast, were the severity of the punishment to which he was doomed, and the fear of being put to death by any one who might chance to meet him in the way. But as banishment, and labour on an unproductive soil, were all that his sentence imported, the Almighty was pleased to favour him with a sign, or token, sufficient to satisfy his mind that the destruction he dreaded should not overtake him; adding, at the same time, that whoever should do him violence, would expose himself to "sevenfold vengeance." What this sign or token was is unknown, and many are the conjectures to which it has given rise. Some think it was a brand in his forehead; others a particular garment with which he was invested; others a continual shaking of his body; others the blasting of his face with lightning; and others the trembling of the ground under him wherever he went.

Descendants of Cain.—Now we behold this fratricide banished in ignominy from the Schechinah, or symbol of the divine presence, and after wandering about through different tracts of uninhabited country, at length settled in the land of Nod, at a distance from Eden, where, it is generally supposed, he became a worshipper of the sun. By the sacred historian no mention has hitherto been made of his wife, who is now first introduced to our notice at the birth of Enoch; although it is extremely probable he was married before he slew his brother and left his father's house. When his progeny began to multiply, he built a city for them, which he named after Enoch, that, by uniting together, they might be the better prepared to repel the hostile incursions which his guilty conscience led him still to dread. From Enoch sprang Irad; from Irad, Methujael; from Methujael, Methusael; from Methusael, Lamech; and from Lamech, Jabal, who constructed moveable tents, and made improvements in the management of cattle, Jubal, who invented musical instruments, and Tubalcain, who discovered the art of extracting iron from its ore.

If it be true, as Josephus relates, that Cain, instead of improving by the afflictions and trials that attended him in his banishment, gave himself up to all manner of wickedness, enriched himself by rapine and plunder, changed the simplicity of former times, and made choice of the most abandoned for his companions, we may easily judge of the bad effects which his example would produce on the conduct of his offspring. We have every reason to conclude that they became licentious, cruel, rapacious, and vindictive. Indeed Lamech, the first polygamist of whom any account is recorded, seems to intimate as much in the following speech to his two wives, Adah and Zillah: "I have slain, (said he,) a man to my wounding, and a young man to my hurt. If Cain shall be avenged sevenfold, truly Lamech seventy and sevenfold." For whether these words be read *affirmatively* or *interrogatively*, they plainly presuppose that Lamech had been chargeable with murder, but that, being less criminal than Cain, who, unprovoked, had assassinated a brother, he might, with much greater justice, expect the divine protection against his adversaries. His wives, it should seem, were sensible of his guilt, and apprehensive of danger, and such was the argument he employed to overcome their fears.

Seth and his descendants.—From the rapidity with which Moses describes the antediluvian ages, many things must be omitted. In the course of 130 years, Adam unquestionably had other children besides Cain and Abel, before the birth of Seth, a fact which is obviously implied in the sacred narrative. We are told by Cedrenus, quoted by Bishop Patrick, that he had 33 sons and 27 daughters, but any specific enumeration ought to be regarded as merely fanciful and gratuitous. Seth was distinguished for his piety and virtue; and from the appellation Enos, signifying *weakness*, which he gave to his first child, we are led to believe, that he deplored the miserable and helpless condition of mankind in consequence of the fall. It is said, that at this time "men began to call on the name of the Lord;" an expression, the import of which, however differently understood by different interpreters, the original words and the strain of the history determine to be this: "men," that is the progeny of Seth, "began to call themselves by the name of the Lord." Very little is recorded concerning his offspring as individuals, before the flood, if we except the duration of their lives, and the place which they occupy in the genealogical catalogue of the patriarchs, from whom the postdiluvians were to descend. Enoch the son of Jared, and Noah the son of Lamech, are the only two whose characters are mentioned with particular approbation. The former "walked with God," and was translated to heaven without tasting of death; and the latter was righteous, and "found grace in the eyes of the Lord." Of the rest we know, in general, that they were attentive to the duties of religion, and were honest and upright in their moral deportment.

Intermarriages, and corruption.—At length the male descendants of Seth, styled "the sons of God," began to associate with the female descendants of Cain, called "the daughters of men;" and enamoured with their beauty and accomplishments, entered into connubial alliance with them, and by incorporating formed one people. Mr Selden, in his book, *De Diis Syris*, relates, from an eastern writer, that the children of Seth, who had sworn by the blood of Abel, never to leave the mountainous parts of the country which they inhabited, to mingle with the children of Cain, were now induced to violate their oath, by the attractive charms of Naamah, and the delightful music of her brother Jubal. The manner in which they were captivated is thus described by the Poet Milton:—

They on the plain
Long had not walk'd, when from their tents, behold
A bevy of fair women, richly gay,
In gems and wanton dress: to th' harp they sung
Soft amorous ditties, and in dance came on.
The men though grave, ey'd them, and let their eyes
Rove without rein, till in the amorous net
First caught, they lik'd, and each his liking chose.

But from whatever cause the union of these two families may have arisen, it is not surprising that it proved subservient to the most pernicious consequences. And if ever the maxim, that "evil communications corrupt good manners," was verified in actual experience, it was so at this period in an awful degree. An almost universal depravity took place; genuine religion was abandoned for idolatry; and the whole earth was filled with impurity, fraud, rapine, and violence. With this the Age of Iron commenced, which is depicted by Ovid in the following lines:—

Protinus irrumpit venæ pejoris in ævum
Omne nefas: fugêre pudor, verumque fidesque;
In quorum subiere locum fraudesque, dolique,
Insidiæque, et vis, et amor sceleratus habendi.
* * * * *
Victa jacet Pietas; et Virgo cæde madentes
Ultima cœlestûm terras Astræa reliquit.

Giants.—From these intermarriages sprang up a race of giants, who were mighty and renowned for their valorous exploits. Not indeed that giants were never heard of until now, for it seems intimated by the inspired historian, that they existed before Seth's posterity united with the posterity of Cain. And we are informed by Sanchoniatho, that from Genus, or Cain, were descended sons of vast bulk and height, whose names were given to the mountains on which they lived. Hesiod also tells us, in his description of the Brazen Age, that the men of that period were fierce, strong, warlike, and insulting; their hearts being of adamant, their corporeal powers immense, their shoulders broad, and their nervous arms irresistible. But though there were such beings in the earth previous to that alliance, yet, in consequence of it they began to multiply, and to present a more threatening aspect. After all, it is very doubtful, whether by giants we are to understand persons of extraordinary *size*, or persons of extraordinary *wickedness*. Both senses may be included in the term, inasmuch as they would naturally become proud and overbearing on account of their prodigious strength; and they were probably the ringleaders in degeneracy during that period of profanity and crime.

Preaching of Noah.—The antediluvians had reached the highest pitch of iniquity; and the Almighty, provoked to indignation, resolved to destroy them with a flood of water, unless they repented of their deeds, and renewed their allegiance to his law and government. He communicated his intentions to Noah, who, amidst the profligacy of the age, was "a just man, and perfect in his generation, and walked with God." To save him and his family, along with a pair of each species of animals, from the impending ruin, he was directed to build an ark of sufficient dimensions for their accommodation. For 120 years, which were allotted for the raising of this huge structure, Noah was commissioned to forewarn mankind of their alarming situation, and to exhort them to reform their lives, and to supplicate forgiveness ere it was too late. Hence he is styled by an apostle, "a preacher of righteousness;" and indeed all the time he was engaged in preparing the vessel, he may be considered as delivering to them one continued practical discourse. But his ministry among them was attended with no success. Ignorant of the divine power, or perhaps trusting to the unwearied operation of divine grace, they disobeyed his exhortations and counsels, as the result of weak and superstitious fear. And thus "because sentence against an evil work was not executed speedily, their hearts were fully set in them to do evil." Such was the plenitude of their awful infatuation.

Destruction by the Flood.—The ark was at length completed, and the period of God's long suffering patience brought to a close. Noah and his family, with the animals accompanying them, entered this asylum, and the Almighty "shut them in," and sealed up the doors. The fountains of the great deep were broken up, and the flood-gates of heaven were thrown open, through which the rain rushed in cataracts to the earth, to inflict vengeance on the guilty and impenitent sons of men. Behold the miserable victims running in every direction from the fury of that storm which they so lately derided! Some cling to the ark and implore admittance; others repair to the roofs of houses; others climb to the tops of the loftiest trees; and others ascend to the summits of the highest mountains; but the impetuosity of the elements drive them from their stations, and the overwhelming waters swallow them up to rise no more. Amid this wreck of nature, this scene of desolation and of death, Noah and his wife, with his sons and their wives, were upborne on the swelling flood; and while thousands fell on their right hand, and ten thousands on their left, they were shielded by the arm of the omnipotent Jehovah, and were preserved to be the progenitors of a new world. The deluge commenced about the beginning of our November, and lasted one whole year.

This event, so particularly described by Moses, is also alluded to by the writers of heathen antiquity. Berosus, the Chaldean, informs us, that Xisuthrus, (another name for Noah,) was warned in a dream of the approaching destruction of mankind by a flood; that he was ordered to build a ship for the protection of himself, his friends and his relatives, together with fowls and fourfooted beasts; and that, in yielding a compliance with that premonition and command, he, and all that were with him, were saved from the ravaging waters. The same story is related by Abydenus, quoted by Eusebius in his *Preparatio Evangelica*. And, to pass over in silence the inundations which happened in the time of Ogyges and Deucalion, and the traditions of a deluge in almost all nations; the memory of this tremendous catastrophe, as the learned Bryant and Faber have abundantly shewn, pervades the whole of Pagan Mythology.

Religion of the Antediluvians.—From what has been already observed, it is evident that the antediluvians were by no means ignorant of the truths and consolations of the gospel. The prophetic promise of the Messiah was given to our first parents immediately subsequent to their fall, and in the accomplishment of this promise they seem to have firmly believed; for, abstracting from other considerations, on what principle can we account for the death of those animals with whose skins they were covered, but on the supposition that they were slain in sacrifice, as a prefiguration of the death and atonement of Christ? In all probability, no beasts had as yet died of themselves; and it is clear, notwithstanding what has been urged by the opponents of this doctrine, that flesh was not used as food before the grant made to Noah after the deluge.

It has been much disputed whether sacrifices, previously to the flood, were of divine institution; and very learned men have arranged themselves on both sides of the controversy. Dr Spencer, Dr Sykes, Bishop Warburton, and others, have adopted the negative of the question; and they have been ably answered by Dr Kennicot in his *Two Dissertations;* Dr Jennings *in his Jewish Antiquities*; and Dr Magee in his work on *Atonement and Sacrifice.* From the cursory manner in which Moses relates the affairs of the antediluvian world it is not to be wondered at, that he says nothing concerning the appointment of sacrificial oblations. Yet, from some of the incidents which come under his notice, we may warrantably infer, that the practice must have arisen not from human contrivance, but from the positive injunction of heaven. How, otherwise, is it possible to understand why God should have refused the sacrifice of Cain, while he accepted the sacrifice of Abel? That of the former consisted only of inanimate objects, namely the fruits of the earth, as an expression of his gratitude for the bounties of providence, without any reference to his ruined condition, or to the blood of the promised Redeemer; whereas that of the latter, besides inanimate eucharistic gifts, consisted also of the firstlings of the flock, as a burnt-offering, to symbolize that expiation which Christ was to make for sin, when the fulness of time should come. Now, since the divine favour was so signally displayed towards Abel on account of his faith, that faith must have had other grounds than the mere conclusions of his own reason on which to rest; inasmuch as God, who is jealous of his prerogative, would have by no means approved of an act of will-worship. Indeed there is nothing in human nature which could lead men *a priori* to suppose, that the Deity would be pleased with the death of his creatures. The truth then seems to be, that sacrifices originated in a divine command, as early as the first mention of Christ; and hence he is represented in Scripture as a lamb that had been slain from the foundation of the world.

The doctrine of the soul's immortality was also known to the antediluvians. It was intimated by the promise of the Messiah to our primeval parents; for, unless this be allowed, it will be difficult to conceive how that promise could impart any real consolation to their minds, under the sentence of death to which they were subjected. It was intimated by the acceptance of Abel, a little before he fell a victim to the fury of his brother, since this acceptance implied blessings in which he could never have participated had he not afterwards existed in another state. And it was intimated with still greater clearness by the translation of Enoch; because, if this was the reward of his walking with God, then he only exchanged earth for heaven, and time for eternity. Nor at this period were mankind uninstructed in the future judgment of the world; the apostle Jude informs us, that Enoch prophesied of that event.

With regard to the Sabbath, some have denied that it was appointed before the giving of the law. But we are told that "God blessed the seventh day and sanctified it, because that in it he had rested from all his works which God created and made." And besides, without admitting that it was instituted at the creation, it will be difficult to assign any reason for the sacredness of the number *seven*, and the portioning of time by the *septenary* revolution of days, which has universally prevailed among the heathen nations. They could not have borrowed this division from the writings of Moses, to which they had no access; nor could they have been led to it by any observations on the motion of the earth, or of the celestial bodies. It cannot, therefore, be accounted for on any other principle but that of tradition.

Form of government.—If Cain's apprehensions of danger on the murder of his brother, and Lamech's speech to his wives, who were afraid of the vengeance which his crimes might provoke from the hand of justice, be excepted, no traces of a civil polity among the antediluvians appear in the sacred page. Yet as such a polity is necessary for the well-being and comfort of society, it is natural to suppose that they must have had a government under some form or other. This was undoubtedly *patriarchal;* the exclusive power being lodged in the fathers of families. Not only would each father be considered as supreme in his own household, but he would also be regarded as invested with paramount authority by all the families who were descended from him. How long such a form existed, it is impossible to say. It may even be fairly questioned, whether it continued to the time of the flood; because men of superior strength and superior acquirements might, by address or compulsion, have gained an ascendancy over the particular sphere in which they moved. Nay it is not unlikely, that, after the union of Seth's posterity with that of Cain, there was no effective government at all; for then the utmost anarchy and disorder prevailed.

Arts, &c.—Although the inspired records give us little information concerning the antediluvian arts, yet we may decypher, amidst the partial darkness in which they are involved, their rudiments or general character. Doubtless, compared with the perfection at which they have arrived in modern times, by the accumulated experience and improvement of nearly 6000 years, they were then in an infant and unpolished state. Husbandry and pasturage were the first objects which engaged the attention of men. Adam was employed in dressing the garden, Cain in tilling the ground, and Abel in grazing the flock. But agriculture implies the use of implements fitted for the purpose; which probably consisted of shells, sharp-edged stones, or pieces of wood whetted at the point. It was not long, however, before these rude implements were laid aside, when the art of Metallurgy was discovered by Tubal-cain. Architecture, carpentry, and music, were also objects of attention; for we are told that Cain built a city, that Jabal constructed tents, that Jubal taught to perform on the harp and organ, and that Noah erected that immense and complicated fabric the ark. The Arabians ascribe the invention of colours and painting to Naamah, and of letters and writing to Seth. And if we may believe Josephus, Seth and his descendants were well acquainted with astronomy and other useful sciences; and being informed by Adam that the world should be destroyed by water, they set up two pillars bearing inscriptions of their knowledge of these sciences, as monuments to future ages. Whether the antediluvians had any traffic we are not told; yet from the progress they made in the arts, and from the hint given us by the sacred historian concerning the introduction of property, or of exclusive right among them in the time of Jabal, it is very likely that they carried on some kind of trade by barter or exchange. Marriage, instituted by the appointment of God, was restricted to one man and one woman; but the original institution was soon transgressed by Lamech, who married two wives, and thus set an example of polygamy which, perhaps, was generally followed, especially among the posterity of Cain.

Longevity.—When we think of threescore and ten years, the present standard of human life, we are apt to wonder at the vast ages which the antediluvians reached. Lamech, the youngest of them who died a natural death, lived 777 years, and Methuselah 969. In almost perfect coincidence with the Mosaic account, Manetho, Berosus, Mochus, Hestiæus, Hieronymus, and many other heathen historians relate, as Josephus informs us, that the first inhabitants of the earth lived even to 1000 years. The causes which led to their longevity are commonly considered to have been the strength of their corporeal powers, the mild and uniform temperature of the air which they breathed, the sobriety of their habits and simplicity of their diet, and the excellent and invigorating quality of the fruits and vegetables on which they fed. But whatever may have been the proximate causes, the ultimate cause was the will of the Creator, who ordains every thing for the accomplishment of the wisest ends. Thus, provision was made for the more speedy propagation of the species, and peopling of the earth; for the transmitting of religious knowledge in a state of purity, in the absence of written document and memorial; and for making discoveries and improvements in those arts and sciences which were useful for the convenience and comfort of society.

In place of admitting such a longevity to the antediluvians, it has been maintained that their lives ought to be reckoned, not by solar but by lunar years, of about 30 days each; an assertion than which nothing more palpably absurd can well be advanced. For, independently of the consideration that it would be impossible to know when to leave off this mode of reckoning, and to calculate by annual revolutions of the earth round the sun; the ages of the patriarchs, in general, would be reduced to a much shorter term than we ourselves attain; even Methuselah would have been only about 80 when he died. Besides, Enos, at the birth of his first son, would have been seven, and Cainan, Mahalaleel, and Enoch, five years old. To this we may add, that if the years after the flood were also lunar, then Abraham had Ishmael in the 7th, and died, "an old man and full of years" in the 14th year of his age. But enough has been said to refute the lunar hypothesis.

As the lives of the antediluvian patriarchs vary according to the different computations of the Hebrew, the Samaritan, and the Septuagint texts of the Bible; and as there have been advocates for each of these computations, we shall here subjoin the following tables: The *first* column denotes the year of the world when the patriarchs respectively began their lives; the *second*, their ages at the birth of their sons; the *third*, the time they lived with Adam; the *fourth*, the time they lived with Noah; and the *fifth*, the time they lived in all.

I. *Hebrew Computation.*

Adam	1				930
Seth	130	130	800		912

III. *Septuagint Computation.*

Adam	1	230			930
Seth	230	205	700		1042
Enos.	435	190	495	113	1340
Cainan. . . .	625	170	305	498	1535
Mahalaleel .	795	165	135	823	1690
Jared	960	162		1220	1922
Enoch	1122	165		947	1487
Methuselah .	1287	187		1881	2256
Lamech . . .	1474	188		2039	2227
Noah	1662	500			

Of these three computations, that of the Hebrew is the most generally received, and is supported by the most respectable authorities. If, according to it, we add 600,—Noah's age when he entered the ark,—to 1056, the age of the world when he was born, the period from the creation to the deluge will amount to 1656 years.

Number at the flood.—It is impossible to arrive at any thing like certainty with regard to the population of the antediluvian world; all that can be stated on the subject is merely conjecture. Yet it is certain, from the general term of the patriarchal lives, that the human race at the flood must have been very numerous. Mr Burnet, supposing Adam and Eve to have left, at the end of the first century, 10 pairs, and taking a *quadruple*, instead of a *decuple* ratio, for the succeeding centuries, gives us 10,737,418,240 inhabitants. Mr Whiston, proceeding on the principle, that mankind began to procreate as early as they do at present, and continued as long in proportion to their ages, and fixing, according to fancy, the period of doubling at irregular and assumed intervals, produces 549,755,813,888. Mr Cockburn, again, who adheres to the Septuagint chronology, after having made due allowance for every circumstance, such as the age of puberty, and the time of nursing, &c. brings out, in one table, with 50 for the period of doubling, 429,496,729,600; and, in another table, with 40 for the period of doubling, 54,975,581,388,800. Whatever result may be adopted as the most probable, it will far exceed the present population of the earth, which is computed at 800,000,000.

On this subject the reader may consult with advantage Patrick *on Genesis;* Shuckford's *Connexions*, Vol. I.; Stackhouse's *History of the Bible*, Vol. I.; and Faber's *Horæ Mosaicæ*.

ANTEGO, an island in the West Indies. See ANTIGUA.

ANTEJURAMENTUM, an opposition of oaths, denominated also *juramentum calumniæ*, or oath of calumny, was an oath which the person who brought an accusation, as well as the accused, was required to swear before trial in ancient times. The accuser bound himself to prosecute, and the accused swore, on the day on which he was to undergo the ordeal, that he was innocent of the crime.

ANTELOPE, the trivial name of different species of quadrupeds belonging to the genus *Capra*. See MAMMALIA.

ANTENNÆ, the horns or feelers of insects which are of an articulate and flexible structure, commonly two in number, and found in all perfect insects with six legs; but in such as have a greater number of legs the feelers are either wanting, or there are more than two, as in the crab and lobster. In thickness, length, shape, and structure, the antennæ exhibit as great diversity as in the form and magnitude of the insects which are furnished with those remarkable appendages; and even in the male and female of the same species, a striking difference often prevails. The antennæ of insects have been variously regarded by naturalists, as the organ of feeling, of smelling, of tasting, and of hearing. But of the real use of those organs, the numerous experiments which have been instituted to ascertain it seem to lead to no positive conclusion.

ANTENOR, a Trojan prince, the son of Laomedon, and the younger brother of Priam, is one of the characters who make a conspicuous figure in the Iliad and Æneid, and is supposed to have settled in Italy after the fall of Troy.

ANTEQUERA, or ANTEQUIERA, a town of Grenada in Spain, although it is said to be included neither under Grenada, Cordova, nor Seville, near the confines of which it stands, is divided into the upper and lower town; the elevated division is occupied by the higher ranks; and the lower town, which covers a fertile plain, watered with numerous streams, is the residence of mechanics and farmers. The waters of a lake on the higher region afford salt by spontaneous evaporation in summer; and the wine called *Mountain* is obtained from the vineyards on the mountainous districts to the southward. The population exceeds 19,000.

ANTHELION, from the Greek, signifying in opposition to the sun, is a luminous spot in the heavens opposite to the real sun, and produced by refraction in a peculiar state of the atmosphere.

ANTHELIX, the interior protuberance of the external ear, of a semicircular form in the inner side, and running parallel to the helix.

ANTHELMINTICS are such medicines as are employed for the expulsion of worms. See MATERIA MEDICA.

ANTHEM, a passage selected from Scripture, and set to music, which is performed by alternate singing in the cathedral service, and it was originally applied both to psalms and hymns; but, in a more limited sense, it is restricted to a sacred musical composition, adapted to a particular solemnity. The anthem was first introduced into the reformed service of the church of England in the beginning of the reign of Queen Elizabeth.

ANTHEMIS, a genus of plants belonging to the Syngenesia class, under which genus are included *sweet chamomile, corn chamomile, may-weed, &c.*

ANTHER, or ANTHERA, is that part of the stamen in the flower of plants which is attached to the extremity of the filament, and is easily recognized by the fine dust with which it is covered as the flower advances in maturity.

ANTHERICUM, Lancashire or Scotch Asphodel, a genus of plants belonging to the Hexandria class.

ANTHOCEROS, or HORN-FLOWER, a genus of plants belonging to the Cryptogamia class.

ANTHOLOGY, from the Greek, signifying a discourse of flowers, or a collection of flowers, is an appellation of a collection of the flowers of poetry, or of beautiful passages from different authors; and it is applied also to a collection of epigrams, taken from several Greek poets.

ANTHOLYZA, Mad-flower, a genus of plants belonging to the Triandria class.

ANTHONY'S, ST. FIRE, is synonymous with Erisypelas or Rose, and is supposed to have derived this name from the power of curing this disease which was ascribed to St. Anthony of Padua.

ANTHONY'S, ST. ISLAND, one of the Cape de Verd islands on the western coast of Africa, is a mountainous district, inhabited chiefly by negroes, and produces abundance of rich fruits, with some cotton and indigo.

ANTHONY'S, ST. FALLS, a grand cataract on the river Mississippi, where the whole body of the stream, which is 750 feet in breadth, falls from the height of thirty feet.

ANTHOSPERMUM, Amber-tree, a genus of plants belonging to the Polygamia class.

ANTHOXANTHUM, a genus of plants belonging to the Diandria class; one species, the *odoratum*, or sweet scented vernal grass, communicates the fine fragrance to hay.

ANTHROPOLITE, from the Greek, signifying *stone-man*, denotes a petrified human body. Among the numerous remains of the organized beings of a former world, whether belonging to the animal or vegetable kingdom, the largest and most perfect quadrupeds, and all parts of plants, the stems, the leaves, the flowers, and fruits, have been found in a petrified state; but the discovery of the petrifaction of a human body is a rare occurrence. The petrified human subject, which was found in a limestone-rock in Guadaloupe, in the West Indies, and, excepting the head, was dug out pretty entire, affords one authentic instance of this remarkable change. This curious specimen was transmitted to Britain by the care of Sir Alexander Cochrane, and is now deposited in the British Museum.

ANTHROPOPHAGI, from two Greek words, which signify *man* and *to eat*, is an appellation applied to those nations who are supposed to be cannibals, or feed on human flesh. In considering the probability of any people, even in the most barbarous period of their history, indulging in this practice from choice, and not driven to it by famine, or actuated by a spirit of revenge, it seems to have been seldom taken into view that few animals feed on their own species. It is not easy to see why man, whose resources are more numerous and various than most other animals, should be excluded from the influence of this natural feeling. But after all the learned discussion to which this fruitful subject of controversy has led, it may be fairly doubted, whether those who are desirous of discovering a true race of cannibals have succeeded in their researches either among ancient or modern times.

The fictions and fabled accounts of the poets and historians of antiquity allude to such a practice; and, in the doubtful narratives of modern travellers, it is asserted that, in China, great markets are furnished with human flesh for the better sort of people; that in some parts of Africa, human legs and arms are hung upon wooden shambles, and exposed to sale like butcher-meat; and commanders of armies, when on an expedition, carry with them young women, some of which are daily slaughtered to gorge the appetites of those supposed cannibals. But when this information, and the sources from which it is derived, are strictly investigated, the inquiry traces the practice to the pressure of hunger, the spirit of revenge, or some superstitious ceremony. Prisoners taken in war are the usual victims of this barbarous repast; and in many cases it seems pretty obvious, that the gratification of the passion of revenge in the celebration of this bloody triumph over the dead body of an enemy, is connected with a religious rite, in which the sacrifice of human beings is considered the most acceptable offering to guardian divinities, or to the souls of departed warriors.

ANTHYLLIS, Kidney-vetch, a genus of plants belonging to the Diadelphia class.

ANTIBACCHIUS, a metrical division in ancient poetry, consisting of three syllables, of which the first two are long and the last is short, as *āmbīrĕ*.

ANTIBES, the ancient Antipolis, a sea-port town of Provence, in France. Salted fish forms the chief part of its commerce; the surrounding country abounds with fruits, the climate is genial, and the population is about 3000.

ANTIBURGHERS, a class of seceders in Scotland, distinguished from the burghers by their opposition to the burgess-oath, or that part of it which is connected with religious establishments. But the name is not considered by the class to whom it is applied as their proper designation.

ANTICHORUS, a genus of plants belonging to the Octandria class.

ANTICHRIST, from the Greek, signifying, in opposition to Christ, or assuming his place, is some personage under this denomination, or that of "the man of sin," referred to in Scripture, who should appear in some period of the world, and concerning whom much controversy and diversity of opinion have prevailed in all ages and countries. But the question yet remains unsolved. Some think that the character applied to this personage in Scripture belongs only to the devil, and that he is the true Antichrist. According to some, Antichrist was to be a Jew, and a descendant of the tribe of Dan; while others attribute that character to the Jewish high-priest and sanhedrim. By the divines of the Romish church who have discussed this point, the emperor Caligula is pronounced to be "the man of sin;" but, among protestant divines, this character is generally attached to the pope. Some apply the denomination, not to an individual person, but to a civil or religious establishment, as to pagan Rome, Judaism, or popery; and others think that Antichrist appears in the three great forms of popery, Mahometanism, and infidelity. One author, whose work, it is said, is deposited in the Bodleian library in Oxford, attempted to prove that Oliver Cromwell was Antichrist; and another, at a much later period, regards revolutionary France as "the man of sin," and Bonaparte as the last head of the beast. From all this vagueness and diversity of interpretation of the passages of Scripture to which this subject refers, the sober-minded may perhaps hesitate in adopting any opinion which has yet been offered; and perhaps the expressions which have been so variously explained, ought to be taken in a figurative sense, and applied to the general conduct of men in wilfully resisting and unreasonably rejecting the doctrines and precepts of Christianity.

ANTICOSTI, an uninhabited island in the mouth of the river St Lawrence in North America, is above 100 miles in length from east to west, and about 25 miles in breadth; is covered with pine trees; has a rocky coast; is well supplied with fresh water; and the soil is fertile, but in many places marshy. The shores abound with cod fish, of large size and excellent quality. The beneficent establishment of a family on this island for the purpose of affording assistance to mariners unfortunately shipwrecked on its coasts, which was at one time projected by the British government, has not yet been effected. N. Lat. 49. 30. and between W. Long. 61. 30. and 64°.

ANTICYRA, a city of Phocis on the bay of Corinth, was ravaged by Philip of Macedon in revenge for the sacrilege of the Phocians in seizing the temple of Apollo at Delphi, during the ten years *sacred war*; fell under the dominion of the Romans when their power extended to Greece, and afterwards became famous for its hellebore, a vegetable production of the mountainous districts in its vicinity, and a fashionable place of resort for invalids to whom that medicine was recommended. Asprosprizzia, or *White houses*, is the modern name, and it enjoys some trade in the exportation of corn.

ANTIDESMA, or Chinese laurel, a genus of plants belonging to the Dioecia class.

ANTIGUA, or Antego, one of the British West India islands, is in N. Lat. 17. 30. and W. Long. 61. 30. about 50 miles in circumference, and includes an area of nearly 69,000 acres, of which about 34,000 acres are destined to the culture of sugar and pasture land. Antigua was discovered by Columbus in his second voyage; but it was quite destitute of inhabitants, when some Frenchmen, driven from St Christophers, in 1628, by the Spaniards, sought a temporary asylum in it; and which, it is supposed, the want of fresh water made them abandon in a short time. In 1732, some English families fixed their residence in Antigua, for the purpose of raising tobacco; but, in consequence of a grant from Charles II. Lord Willoughby established a more efficient and more numerous colony, whose prosperity was checked by an invasion of the French and Caribs from Martinique, and their property pillaged and destroyed. Restored to Great Britain at the peace of Breda, in 1668, and aided by the experience of some planters from Barbadoes, who settled in it in 1674, this island, under all its disadvantages, began to rise in value, when the soil was found suitable for the cultivation of the sugar-cane.

The districts on the southern parts of the island are mountainous, but no part of it rises to any great elevation. Two kinds of soil predominate, one of which, a black mould on a subsoil of clay, is rich and fertile, when the crop escapes the severe droughts which are not unusual in the climate of Antigua; and the other, a stiff clay on a marly subsoil, is less productive, and is soon impoverished by culture. No springs but such as yield a brackish water flow in Antigua, and no rivers water its vallies. To compensate for this serious inconvenience, rain-water is collected in large cisterns; and when the rainy season is not unusually abridged, a sufficient supply is obtained. The harbours are safe and commodious. English-harbour, where a royal dock-yard and arsenal have been established for careening and repairing ships of war, is capable of admitting those of the largest class.

St John's is the chief town, and capital of the island, which is divided into six parishes, which are served by five rectors, who are provided with annual stipends from L.660 to L.450 currency. Four Moravian missionaries have four chapels in the island, and nearly 9000 slaves under their ministry; and two preachers of the Methodist persuasion have three places of worship. Some of the white inhabitants are Roman catholics, but have no chapel or resident priest. A governor or captain-general, whose authority extends to several other islands, with a council of twelve members, and an assembly of twenty-five members, compose the legislative body of Antigua. The judicial establishments are assimilated to those of the parent country.

Sugar and rum, the staple productions of Antigua, which, either from ignorance of the culture of the cane, or from the imperfect mode of manufacture, were, in the infancy of the colony, unfit for the British market, are now so much improved as to be equal in quality to similar produce from any other of the West-India islands. The uncertain climate renders the sugar crop precarious; but 17,000 hogsheads, of 1600 pounds each, with the usual proportion of rum, is reckoned an average crop. Some cotton is raised, and dye-woods are enumerated among the exports.

From a census, under the authority of the colonial legislature, in 1811, it appears, that the number of white inhabitants was 2102, exclusive of troops; the number of free persons of colour was 1747, and of free blacks 438; and of slaves 28,317. The slave population, in 1807, when the slave-trade was suppressed, amounted to 30,282, from which it would seem, that a decrease, approaching to a tenth part of the whole, had taken place in three years. But Governor Elliot, suspecting some inaccuracy in the statement, had the enumeration brought down to January 1812, when the number entered at the public office amounted to 30,968, which, with 484 who had obtained their freedom within the same period, shews an actual increase of 1170 slaves since the abolition of the trade in 1807. This corrected statement affords a gratifying prospect to the friends of humanity in the improved condition of the slaves, and must also prove satisfactory to the planter, who sees the number of his labourers increased under his fostering care without foreign importation. The same valuable document notices the progressive approach of some part of the negro population to the rights of citizenship. Of the free black persons, 148 are proprietors of lands and tenements, are under no restriction in the purchase of heritable property or slaves, and have the privilege of voting for the election of a representative in the House of Assembly, in the same manner as white freeholders. Another portion of the same description of persons possesses the same privileges, excepting the right of voting, and the purchase of land exceeding ten acres; and the testimony of all free persons is admitted in the criminal and civil courts of the island. The whole population of Antigua, in 1812, amounted to 35,255; and the estimate of the number of the slaves in 1787, drawn from erroneous information, and stated in the general sketch of America at page 259, must be corrected.

ANTIHELIX, or ANTHELIX, a protuberant portion of the external ear in man.

ANTILLES, the French designation of the West-India islands. By some geographers they are divided into Greater and Lesser Antilles. Cuba, St Domingo, and Porto Rico, belong to the first division, and all the others are included under the second, or the Lesser Antilles.

ANTIMONY, the *Stibium* of the ancients, a brittle metallic substance, which has been long the subject of chemical research, was at one time prohibited from use in France on account of its supposed poisonous properties, and, at another, was regarded as one of the most valuable medicines, is now chiefly limited in its use to the purpose of an alloy with lead in printers types. See CHEMISTRY and MINERALOGY.

ANTINE, FRANCIS D', the celebrated author of a chronological work, was born at Gourieux, in the territory of Liege, in 1688, studied at Douay, and, in 1712, assumed the monastic habit. He taught philosophy for some time at Rheims; and the object of research, in which he was long occupied, as compiler and editor of the *Decretalia* and *Glossarium Scriptorum Medii Ævi*, probably suggested the plan of a most elaborate undertaking, *L'Art de verifier les Dates*, or the "Art of fixing the dates of Events," which he commenced, and had proceeded far in its compilation, when he was seized with apoplexy, which, after repeated attacks, terminated his life, in the year 1746. What was left unfinished by the author was completed, and the work was published. The third edition, in three large folio volumes, which is esteemed the best, was printed at Paris between 1783 and 1787. This valuable work exhibits a chronological view of ancient and modern history, a list of sovereigns or rulers of kingdoms and states, with the time of their accession, a catalogue of eclipses of the sun and moon since the birth of Christ, lists of councils, calendars of saints, with the record of all other memorable transactions from which the date of past transactions may be ascertained.

ANTINOMIANS, from the Greek words signifying "in opposition to the law," are those who deny the obligation of the moral law under the gospel dispensation, or who maintain doctrines which seem to supersede the necessity of good works and a virtuous life in those who profess Christianity. The charge of holding such opinions was brought by Luther against John Agricola and his followers in Germany, in 1538, and this appellation was bestowed upon them by the great reformer. But as they were inferences which were supposed to follow from his doctrine, rather than any positive expression of his principles, the imputation was disclaimed by Agricola, whose opinions did not embrace morality in general, but the laws of the ten commandments, which he considered as addressed to the Jews only, and now superseded by the dispensation of the gospel.

Opinions of a similar character were propagated in England in the time of Oliver Cromwell; and by some of those who maintained them it was expressly declared, that the elect cannot fall from grace, or forfeit the divine favour, and, as their wicked actions are not really sinful, forsaking sin, confession, and repentance are not considered essentially necessary to salvation.

ANTIOCH, an ancient city of Syria, which stood on the banks of the river Orontes, about twenty miles from the place of its junction with the Mediterranean, was built by Seleucus Nicator, received the name from that of his father, and became the residence of the Macedonian princes, under whose dominion that part of Syria was reduced. The wealth and magnificence of this famous city obtained for it the splendid appellation of the Queen of the East, a character which belonged to it for the long period of 1600 years; but from its origin, three hundred years before the Christian era, till its final decay, the records of its history are filled with a crowded detail of the calamities of war, and famine, and pestilence, of civil commotions, fire, and earthquakes, while the inhabitants, during the intermediate gleams of prosperity, when it recovered its splendour, were immersed in every kind of luxury and dissipation. After the fall, or extinction, of the race of its first sovereigns, the Romans, the Persians, the Saracens, and the Turks, became successively masters of Antioch. Having withstood a siege of eight months, it was taken at the end of the eleventh century by the Duke of Normandy, in the time of the crusades; and in 1262 it fell under the dominion of the Sultan of Egypt. It is vaguely stated that the population, in the most flourishing periods of its history, exceeded half a million.

The modern Antioch, which stands on the southern banks of the Orontes, is described by recent travellers in a ruinous condition, the houses built of mud and straw, the streets narrow and dirty, and exhibiting altogether a melancholy picture of misery and wretchedness. It is forty miles southwest from Aleppo. The soil of the surrounding country is fertile, but neglected; and the feeble industry of the inhabitants is limited to the management of a few plantations of vines, olives, figs, and mulberry trees,

ANTIPAROS, the Oliaros of the ancients, is an island of the Grecian Archipelago, and, as the name imports, is opposite to Paros, from which it is divided by a strait, which is scarcely a mile in breadth. It is about sixteen miles in circuit, produces some wine, cotton, and corn, and the greater proportion of the inhabitants, about 400 or 500, is collected in a village at one extremity of the island.

A spacious natural grotto, or cavern, supposed on doubtful authority to have been known to the ancients, and which was brought into notice in the 17th century by an Italian traveller, has given great celebrity to Antiparos, and rendered it an attractive object to future travellers. It was first particularly described by the learned French naturalist, Tournefort, and the visit of Mr Saunders, an Englishman, is minutely detailed in the British Magazine for 1746. But vast and magnificent as this cavern assuredly is, some abatement must be made of the awful horrors and splendid beauties which it exhibits to the intrepid visitant. The entrance is at the side of a low hill in the centre of the island, and the immense excavation is in a mass of limestone, or marble, which is probably the prevailing rock. It is nearly 1000 feet in length, more than 300 feet in breadth in some places, and the deepest part is 250 feet below the surface of the earth. The whole is adorned with innumerable columns and pilasters attached to the sides, depending from the roof, or rising from the floor. These columnar structures owe their formation to the filtration of water, holding lime in solution, through the superincumbent strata, and either dropping from the roof, or passing along the sides, the lime is deposited as the water evaporates, and thus, as the rapidity of the process is greater or less, all the variety of forms is produced.

The older naturalists, in describing stalactitical processes, made a distinction between the columnar mass formed from the roof, and that which arose from the floor of petrifying caves. The first was called *stalactite*, and the last *stalagma*, as having dropped from above. As the process proceeds, the stalactite increasing in length from the roof downwards, and the stalagma by the continued deposition of earthy matter from the water as it drops, shoots upwards, and the two at last uniting, form one entire column.

A stalagmitical concretion, without a counterpart from the roof, has been distinguished by the name of *altar* for a century and a-half, in consequence of a grand celebration of mass which was conducted in presence of the French ambassador to the Ottoman Porte in the year 1673, and an assembly of 500 persons. This magnificent natural altar, the gradual production of many ages, is more than 20 feet in height and not less in diameter. The grotto was illuminated with 100 torches; 400 lamps were kept continually burning during the whole of the impressive ceremony; and an inscription on the base of the consecrated pillar records this remarkable celebration of mass at midnight of Christmas in the year 1673.

ANTIPAS Herod, a son of Herod the Great and of Cleopatra, a native of Jerusalem, was nominated, by his father's first will, the successor to his dominions, but a new destination appointed his brother to share his territory. By the decision of the Emperor Augustus, to whom the disputed right was referred, the greater part of Galilee and the country beyond Jordan fell to Herod. The strength and security of his kingdom were the first objects of his government. He adorned and fortified the principal towns, and built a fine city on the banks of the lake Genneserat, which, in honour of the Emperor Tibeberius Cæsar, was named Tiberias.

The wife of Herod Antipas was the daughter of Aretas, king of Arabia. A passionate attachment for Herodias, his brother's wife, and his purpose of divorcing his own, induced the latter to throw herself under her father's protection. Herod married Herodias, and was involved in a disastrous war of four years duration with the Arabians. The Jewish nation were offended at his marriage, which was considered unlawful; the expression of censure which his conduct drew from John the Baptist, excited the resentment of Herod against that prophet; and, at the instigation of Herodias, John was thrown into prison and beheaded. When Jesus Christ was brought before Herod by the order of Pontius Pilate, he was treated with every mark of indignity, clothed with a white robe as a reproach, and sent back to the governor of Jerusalem.

Herod Antipas, ambitious of the title of king, which his nephew Agrippa Herod had obtained from Caligula, made a journey to Rome to prefer his suit to the emperor. His request of being invested with regal dignity was not only rejected, but he was stripped of his government, banished to Gaul, and died in Spain, where he spent the last days of his life. Mark vii. Luke xxiii.

ANTIPATER, a celebrated Macedonian general, first under Philip and afterwards under his son Alexander the Great, was much distinguished by his prudence, fidelity, and bravery, in the councils and military enterprises of the Grecian hero; and, after the death of Alexander, assumed the government of Macedonia and some contiguous provinces. Antipater was the pupil and friend of Aristotle, and was greatly respected among his countrymen for his literary attainments. He died 320 years before the Christian era.

ANTIPATER, the son of Antipas, governor of Idumea, and the father of Herod the Great, was deeply concerned in the long contested struggle between the brothers, Aristobulus and Hyrcanus, for the office of high-priest in Judea, and, after the restoration of the latter to the pontifical dignity, by the command of Pompey, obtained the chief influence in the direction of Jewish affairs. Julius Cæsar, as a reward for his faithful services, conferred upon him the rights of a Roman citizen, and appointed him to an important official situation in Judea; and in his administration his piety, justice, and patriotism were peculiarly conspicuous. But the Jews became jealous of his power, a conspiracy against his life was formed and discovered; and although the parties concerned were pardoned, they succeeded in bribing a menial servant to destroy him with poison, which was accomplished 43 years before the Christian era.

ANTIPATHES, a genus of zoophytes, including various marine productions, which, from their resemblance to vegetables, are denominated *sea-cypress*, *sea-heath*, and *sea-fennel*. See Helminthology.

ANTIPATHY, derived from the Greek words, signifying *against* and *passion*, is defined a strong aversion which is excited in a sentient being by the presence of certain objects, and is set in opposition to *sympathy*. In attempting to trace the origin of antipathies, moral and physiological writers discover no small degree of diversity of opinion, whether the dislike or painful feeling produced by the sight of certain objects, the smell of some substances, the taste of others, or the hearing of peculiar sounds ought to be ascribed to some instinctive principle, or merely to the power of habit. Some animals, it has been observed, have an antipathy or aversion to the sight of others, as the sheep, which is terrified at the appearance of the wolf; but here a sense of danger begins to operate from the presence of an enemy. In the same way a whole brood of chickens, warned perhaps by the parent, flee for safety when the hawk is seen hovering above them. The aversion to the toad and serpent, which many persons are unable to repress, may proceed from early impressions of the supposed poisonous nature of those animals; and the strong dislike to particular kinds of food, may arise from disagreeable effects formerly experienced from the use of such substances or those of a similar nature. Certain odours may produce, in persons whose sense of smelling is peculiarly delicate, headache and sickness; and, to a nice musical ear, singing out of tune, or the performance on a harsh instrument, is attended with very unpleasant sensations. But the indulgence and strong expression of such aversions render them habitual, and easily excited by association, when similar odours are presented or analogous sounds are heard.

It some cases it may no doubt be difficult to account for the antipathy or dislike which arises from the impression of certain objects on the senses; but in many it may be suspected that it proceeds from caprice, or an affectation of singularity and excessive refinement, as in the instance of a lady whose sense of smelling was so extremely delicate as to be altogether overpowered by the fragrance of a single rose in the same room, and actually fainted away at the sight of an artificial flower.

ANTIPODES, from the Greek words *opposite* and *feet*, is expressive of the position of the inhabitants of the globe who live diametrically opposite to each other. They are under the same meridian and under the same parallels of latitude, but on opposite sides of the equator. The days and nights are of the same length to the antipodes on different sides of the earth, but in opposite seasons. It is noon with the antipodes of the southern hemisphere, when it is midnight with those of the northern; and the longest day of the antipodes of the northern hemisphere is the shortest with those of the southern.

ANTIQUARY, a person who investigates and studies the remains of antiquity, as statues, inscriptions, coins, medals, implements of war and of the arts, edifices public and private, fragments of history, manners, &c. Societies have been established in different countries for the encouragement and prosecution of such researches; but it has rarely happened that institutions of this kind have fulfilled the expectations of the public; and perhaps it requires a much wider range of scientific acquirements than is generally imagined for the successful investigation of the history of remote ages,—a comprehensiveness of view, and a nicety of discrimination, which the admirers of a rusty piece of armour, an old coin, or the insulated fragment of an ancient building, are little aware of, and seldom possess, however pompously they assume to themselves the designation of antiquary.

If indefatigable industry and powerful genius be requisite in the composition of modern history, and in the delineation of modern manners, the materials of which are accessible, how much more necessary is the vigorous exertion of similar talents in rearing a solid and connected superstructure from broken and detached fragments, or what Lord Bacon has forcibly denominated the *wrecks of history*? He who is unacquainted with the general history of an ancient nation, can make no satisfactory progress in studying the manners, the customs, the dress, or the buildings of that nation, and the changes induced by war, emigration or trade. One branch of the objects of antiquarian research serves to elucidate another. The literature of ancient Greece and Rome throws light on the arts and political establishments of these renowned states; and a knowledge of their manners and institutions, illustrates the noble monuments of genius displayed in these historical and poetical compositions which have escaped the ravages of time and the destructive hands of barbarians.

The utility of the study of antiquities, when it is prosecuted with competent talents and rightly directed, is sufficiently obvious, not only in giving consistence and connexion to the history of any ancient people of whose arts or learning memorials are preserved, but it is not less conspicuous in aiding inquiry to retrace to a certain origin many of the institutions of modern nations, and some of the peculiar usages around which time has thrown a dark veil, which can only be penetrated by the reflected light of co-existent objects. The reproach and ridicule to which the labours of the antiquary have been sometimes exposed by those whose objects of pursuit are different, may appear in some degree merited in considering the superficial nature of his researches, which lead to no useful application, and seem to be altogether unproductive. But it ought to be recollected that he who digs the stone from the quarry, although inferior in dignity to the architect who designs and arranges the different parts of a fine edifice, is still a necessary agent in rearing the superstructure; and the mere collector and preserver of a fragment of the wrecks of history may contribute something to its elucidation.

ANTIRRHINUM, Snap-dragon, or Calves-snout, a genus of plants belonging to the class Didynamia, some of the species of which are natives of Britain, and others are the well known ornaments of the flower-garden.

ANTISCII, from two Greek words, signifying *opposite shadows*, is a geographical term applied to the inhabitants of the globe whose shadows at noon fall in opposite directions. The shadow of the inhabitants of the northern hemisphere at noon is projected to the north, and that of the inhabitants of the southern hemisphere towards the south; and they are said to be *Antiscii* to each other.

ANTISEPTICS, a general appellation of those substances which are employed in the preservation of animal and vegetable matters. Saline substances, of which the most common and best known is sea-salt, are applied to this use; but saccharine and aromatic substances are successfully employed for a similar purpose. See DIÆTETICS.

ANTISPASMODICS is a term applied to those medicines which are employed in the cure or prevention of spasms. See MATERIA MEDICA and MEDICINE.

ANTISTHENES, a Grecian philosopher, and the founder of the Cynic sect, flourished about 420 years before the Christian era, was the disciple of Socrates, and seems to have been more anxious to put in practice the precepts of his master with regard to virtue and moderation than to indulge in speculative discussions. But in the exercise of frugality and temperance, his manners became repulsive and morose; and even his indifference in disregarding and despising the accommodations and comforts of life, displayed no small degree of ostentation. "I see your vanity," said his master Socrates, "through your tattered garments."

A place called *Cynosargum*, or the temple of the white dog, without the walls of Athens, was chosen by Antisthenes for his school, from which, as some suppose, the name of the sect is derived; but, according to others, it is indebted for its origin to the snarling and capricious manners of the philosopher.

The unsparing severity with which Antisthenes censured the faults and follies of others, the rigid self-denial which he inculcated, and the moroseness and gloom which overspread all his actions, limited the number of his disciples and followers. Regarding pleasure as the greatest evil, he indulged only in the plainest food, wore a single cloak of the coarsest cloth, and wandered about with a wallet and staff, the whole extent of his property, like a common beggar. He was the author, it is said, of many books; and if the sentiment quoted by Cicero from some part of his works be really his, that "the gods of the people are many, but the God of nature is one," he seems to have held correct notions of natural religion.

ANTITHESIS, from the Greek words which signify to *set opposite*, is the contrast or opposition of words, or expressions, in speaking or writing, for the purpose of marking the difference more strongly. This mode of composition was not uncommon among the ancients, and was very frequent among the older English writers. Cicero affords a good example of antithesis in one of his orations, when he says, "On one side stands modesty, on the other impudence; on one fidelity, on the other deceit; here piety, there sacrilege, &c. The following is an example in poetical composition.

Tho' deep, yet clear; tho' gentle, yet not dull;
Strong, without rage; without o'erflowing, full.

ANTITRAGUS, a protuberance of the cartilage of the external ear in man.

ANTONINUS PIUS, a celebrated Roman emperor, was descended from a noble family in Gaul, and was born at Lavinium, near Rome, in the 86th year of the Christian era. His father and grandfather had enjoyed the consular dignity, and his maternal grandfather, under whose care he was educated, had risen to the same distinguished rank. Possessed of great wealth and influence, which he derived from his rich and powerful relations, he was called to fill various official situations in the state; in the year 120 was appointed consul, became afterwards proconsul of Asia, and in 138 was adopted by Adrian as his successor. The death of Adrian in the following year opened his way to the throne, and he assumed the reins of the imperial government amid the undivided acclamations of the senate and people. The mildness of his character, or his regard for religion, obtained for him the sirname of *Pius;* he merited and was honoured with the titles of *High Pontiff*, and *Father of his Country;* and the prudence, equity, and disinterestedness which marked his administration, and the peace and prosperity which his government secured to the empire, shewed that he was worthy of such distinguished appellations. He resided almost constantly in his capital, and although he was anxious to avoid laying new burdens on the people, and frugal in the public expence, yet he was liberal in gratifying the desires of his subjects for shews and spectacles; and he erected various ornamental and useful public edifices, among which are enumerated the temple dedicated to his predecessor, Adrian, in Rome, and the magnificent structures of the amphitheatre and aquæduct at Nismes in France.

The celebrated wall, of which some remains are still visible, and which extended from the Frith of

Forth to the river Clyde, in Scotland, was erected about the year 140 by the orders of Antoninus. The modern appellation of this rampart is *Graham's dyke*, supposed to be corrupted from *Gryme* or *Grym*, which signifies *strong*, or is the name of the warrior who made an irruption into the Roman territory. When this great military structure was entire, it consisted of a ditch 40 feet wide and 20 feet deep, and a rampart on the south side 24 feet thick and 20 feet in height, with a military way behind it. The whole length exceeded 36 miles; and as a defensive work against the Scots and Picts, which was the object of its construction, it was strengthened by 21 forts, which are supposed to have been erected by Agricola. The materials of which the rampart was composed, seem to have been dug out of the ditch on the north side; for when it passes through rocky strata the proportion of stones is increased. But for a fuller description of this famous wall, the reader may consult Gordon's *Itinerarium Septentrionale*, Horsley's *Britannia Romana*, or Roy's *Military Antiquities of the Romans in North Britain*.

The wife of Antoninus was Annia Faustina, the daughter of Annius Verus, a woman of licentious character, to whom the weakness or indulgence of a husband, who survived her, permitted divine honours to be paid after her death. Two sons and two daughters were the offspring of his marriage. The sons died in early life, and the younger daughter, Faustina, was married to Marcus Aurelius, who, at the desire of Adrian, was adopted by Antoninus, and succeeded him on the imperial throne. After a pacific reign of 23 years, Antoninus died in the 75th year of his age. Accompanied by the most splendid funeral ceremonies, his body was consigned to the tomb of Adrian, and divine honours were paid to his memory.

ANTONOMASIA, a form of expression, in which an official or professional denomination is put for a proper name, or a proper name is put in place of an appellative; as when the king is called his *majesty*; the *philosopher*, for Aristotle; the *orator*, for Cicero; or when a grave man is called a *Cato*, and a wise man a *Solomon*.

ANTRIM, a county in the province of Ulster, in Ireland, bounded on the north by the northern ocean, on the east by the Irish channel, on the south by the county of Down, and on the west by Lough Neagh and the river Bann; is about 56 miles in length and 30 miles in breadth, and includes an area of 970 square miles. The mountainous districts of this county are towards the east and north, but no part of the elevated land rises to a great height. Knocklayd in the north, Slenish in the middle of the county, and Devis, near Belfast, are the principal mountains. The prevailing rocks in the county of Antrim are basalt, limestone, and in some places sandstone. Gypsum is dug out, for exportation, near Belfast; coals have been long wrought at Ballycastle, on the northern coast; the shores of Lough Neagh furnish masses of petrified wood; and pearlstone, a rare mineral production in the British islands, is found at Sandy Brae, 20 miles from Belfast. But the stupendous range of basaltic strata, exhibiting, in many places, magnificent colonades, particularly at the celebrated Giants' Causeway, and stretching almost the whole length of the northern coast, forms the most striking object to the geologist. The northern and eastern districts are destitute of wood, and much of the low grounds is covered with marshes; but in the southern parts of the county the surface is clothed with thriving plantations, and the soil is richer, more fertile, and better cultivated. The Lagan, which falls into the sea near Belfast, is part of the southern boundary, and is navigable to a considerable distance inland, and the Bann, famous for its salmon-fishery, are the chief rivers. The principal towns are Belfast, Carrickfergus, Lisburn, Ballimena, and Ballimoney. Cairns, cromlechs, and mounts, are enumerated among the remains of antiquity in Antrim; and three round towers, those singular structures, the purposes of which have hitherto baffled the researches of antiquaries, are yet to be seen in the county.

Population, manufactures, &c.—In 1788, the population was estimated, perhaps on vague authority, at 160,000; but, according to the *Statistical Survey* of Mr Dubourdieu, the county of Antrim contains 240,000 inhabitants, many of whom are descended from natives of Scotland. No county in Ireland includes a larger proportion of presbyterian protestants. As the manufacturer and tiller of the ground are often united in the same person, the farms are small, and agriculture has not reached its highest degree of improvement. Flax, potatoes, barley, and oats, are the chief crops. The cattle are of small size; the mountainous pastures feed numerous herds of goats; and the rearing of swine is extensive and profitable. Seventy thousand, of 200 pounds each, have been exported from Belfast during the salting season in a single year.

The staple manufacture of the county of Antrim is linen, which has long flourished; but has given place to that of cotton, which occupies between 20,000 and 30,000 of the inhabitants in the vicinity of Belfast and the surrounding country. Kelp is manufactured on the shores of Antrim, and at Carrick-a-rede, a singular spot on the eastern coast, an extensive salmon fishery is successfully prosecuted. A frightful chasm, sixty feet in breadth, separates the island from the mainland; and to facilitate the communication for the convenience of the fishery, a bridge, formed of strong ropes, covered with boards, is annually constructed.

Rathlin island, five or six miles long, and nearly a mile broad, which lies a few miles off the northern coast, is included in this county. The prevailing strata are limestone; the inhabitants are estimated at 12,000; and they are occupied in agriculture, fishing, and the kelp manufacture. To Antrim also belongs Ram island in Lough Neagh, on which one of the round towers of doubtful origin and use, already alluded to, is erected.

The assizes, elections, &c. are held at Carrickfergus, and the quarter-sessions at Antrim. Five members are returned from this county to the Imperial parliament, two of whom are chosen by the county, and one each for Belfast, Carrickfergus, and Lisburn.

ANTRIM, a town of the county of the same

Antwerp.

name in Ireland, enjoys a fine situation on the banks of Lough Neagh, is 84 miles north from Dublin, and 12 miles north-west from Belfast; the inhabitants are chiefly engaged in the linen manufacture; and the surrounding scenery is adorned with the beautiful domain of the Earl of Massareene.

ANTWERP, a city of the Netherlands, and included in the new kingdom of that name, stands on a wide plain on the eastern bank of the Scheldt, is seventy-five miles south from Amsterdam, and twenty-five miles north from Brussels; and from its local position, with ready access to the ocean on one hand, and an easy communication with the interior of the continent by means of rivers and canals on the other, has often risen to the highest commercial prosperity. About the middle of the 15th century the trade of Antwerp was extremely limited; but, towards its close, it became the rival of Bruges, afterwards the emporium of the Portuguese trade to the east, and, by the establishment of great fairs, attracted mercantile adventurers from every part of Europe. In the middle of the 16th century, 2000 vessels have been seen at one time in the port of Antwerp. But the wars of the Low countries checked its growing prosperity, the persecution of the Protestants drove many of the most enterprising inhabitants to seek an asylum in England and Holland, and the commercial influence of the Dutch cut off its communication with the ocean by means of the Scheldt. Excluded from foreign commerce, the industry and resources of the inhabitants were directed to manufactures. Lace, tapestry, silk, and woollen stuffs, and an extensive hat manufactory, occupied a considerable proportion of the population; and the establishment of banking and assurance societies has been long an abundant source of profitable speculation. The occupation of Antwerp by the French during the revolutionary war, and the unrestricted navigation of the Scheldt, gave a temporary activity to the commerce of Antwerp, and its local advantages seemed favourable to the ambitious schemes of Bonaparte, who had projected many great works for its improvement, and had selected it as one of his chief naval arsenals, for which purpose the breadth of the river, which is nearly half a mile, and the depth of water from 20 to 40 feet, render it peculiarly appropriate.

The streets and squares of Antwerp are numerous, and many of them are spacious and elegant. The public edifices are distinguished by their magnificence; the exchange is a superb structure; and the cathedral is a noble pile, with one of the finest steeples in the world. The abbey of St Michael, and some of the other churches, are enumerated among the splendid ornaments of the city; and the storehouses and cellars connected with the house of the Hanse towns, which were filled with all kinds of merchandise, in the flourishing period of its history, are altogether unequalled in any other commercial city. Antwerp is surrounded with strong walls, and defended by a citadel, which were erected about the middle of the 16th century. The reverses to which this city has been subjected, have been particularly marked in the decline of its population, which, in the height of its commercial prosperity, was estimated at 100,000, and even double that number according to some calculations. It had decreased to 50,000 a few years ago; but the re-establishment of peace will give new vigour to the enterprise of the inhabitants, and in a short time add to their number.

Anubis || Anvil.

ANUBIS, an Egyptian deity, worshipped under the figure of a man with the head of a dog, is supposed to be a symbolical image, derived from astronomical observations, and intended as a sensible expression of certain appearances or changes of the heavenly bodies. The mythological history of Anubis has been variously explained, both by ancient and modern writers. The Egyptians worshipped the sun under this name when he appeared in the horizon, or at his rising and setting; and to denote the glowing beauty of the morning and evening, the image of Anubis was of pure gold. The dog, the emblem of fidelity, was consecrated to Anubis, because that deity, the symbolical representation of the horizon, is the faithful attendant of Isis or Nature, seeking her lost Osiris, or the sun. The diminished solar influence, in winter, was represented by processions, in which the priests, with tears and lamentations, carried about the images of Isis and Anubis; and Isis, by the help of Anubis, having recovered Osiris, the discovery was celebrated with every expression of joy and exultation.

ANVIL, a solid mass of iron, of a square form, on which malleable metals are hammered. Cast-iron anvils are sometimes employed, but when a bright surface and great hardness are required, forged iron, faced with steel, is preferred. The forge for the construction of anvils is similar to the common smith's forge, but with single bellows; and coak, which affords a strong heat and produces little flame, is used for fuel. A crane, which moves on a pivot, and transfers the red hot masses of iron from the fire to the anvil, is fixed near the hearth. The anvil is a mass of cast metal, raised about a foot from the ground, and eighteen inches square on the face.

The common smith's anvil is composed of seven pieces; the body, or core; the four corners, for enlarging the base; a projection at one end, in which a square hole for a chisel is formed; and a beak of a conical shape, for rounding hollowed work. The body is formed by welding several smaller masses together, and when it is heated for the purpose of uniting the other pieces, three holes, about one inch square and two inches deep, are first made, one in the bottom and one at each end, for inserting a bar of iron connected with the crane, and thus enabling the workmen to manage the heated mass. The different pieces are separately welded to the core, and when they are large two hearths are requisite. All the pieces being united, the heating and hammering are repeated till the anvil has acquired its proper shape.

Facing with steel is the next operation. A plate of steel, as thin as it can be firmly welded, for when it is too thick it is liable to crack in the hardening, is first prepared, of the size of the anvil. The anvil is brought to a strong welding heat in one fire, and the steel is heated in another, but to an inferior degree. The masses being heated, the uniting surfaces are brushed, laid together, and rapidly hammered. In the process of hardening, the face of the anvil is brought to a full red heat, and suddenly plunged and moved about in a large quantity of water, or, what answers the purpose of cooling better, exposed to a copious stream. The face is then ground perfectly even; and when it is intended for the planishing of metals, it must be finely polished with emery and crocus.

ANVILLE, John Baptiste Bourignon, D', a celebrated geographer, was born at Paris in July 1697, discovered at a very early age a strong passion for the study of his favourite science, and even in his twelfth year, while he was engaged in reading the classic authors, he began to construct maps for the illustration of the countries to which they refer; and such was his successful application, that the maps, which he delineated and published about the twenty-second year of his age, were universally admired.

The elucidation of ancient geography occupied a large share of the industry of D'Anville; and as his materials were chiefly drawn from books of history and travels, his indefatigable labour in collecting them, and sound judgment and nice discrimination in their arrangement and distribution, were conspicuous in all his works, and in a remarkable degree supplied the want of astronomical observations and geometrical measurements. Of the numerous maps which he published many are accompanied with memoirs, detailing the authorities on which he proceeded in their construction. Towards the close of a long life he was admitted to share those honours which are connected with the associates of learned societies. He became a member of the Academy of Inscriptions and Belles Lettres, and contributed many memoirs to their transactions; he was nominated to fill the only place in the Academy of Sciences which is appropriated to the science which he cultivated and adorned, and about the same time he was appointed geographer to the king. The valuable and extensive collection of charts and maps which D'Anville had made in the long course of his study was purchased by the king, and it was the last undertaking of the laborious geographer to arrange it. This task was scarcely completed when his mental vigour declined, and, having reached the 85th year of his age, he died in January 1782.

With a feeble constitution, but with temperate and regular habits, united to great gentleness and mildness of character, D'Anville was able to devote, during sixty years of his life, from twelve to fifteen hours of daily application to study. His recluse manners, and undivided attachment to one pursuit, seem to have contracted his views, for he rarely took part in conversation, excepting on the subject of geography, and here he was impatient of contradiction, and is charged with rudeness in expressing his opinion on controverted points. His *Ancient Geography*, 3 vols. 8vo. is one of the most popular of his works.

ANZIKO, a kingdom on the western coast of Africa. See Ansiko.

AONIDES, an appellation of the muses, which is sometimes employed by the poets of antiquity, and is derived from Aonia, a district of ancient Bœotia. *Aonian* grove and *Aonian* spring have a similar origin.

AORIST, from the Greek, and signifying *without limitation*, is a tense in verbs which is understood by some grammarians to be expressive of an action *indefinitely*, without regard to past, present, or future time, but it is usually restricted to indefinite *past* time. The Greek verb has two aorists, the first, according to some writers on grammar, denoting past time generally, and the second signifying indefinite past time; while others maintain that both have the same meaning, and that the second Greek aorist is the imperfect of some obsolete theme of the verb, and is altogether redundant.

AORNUS, or Aornos, a hill fort in the vicinity of Bijore, in the East Indies, holds a conspicuous place in ancient history on account of the brave defence of the natives when they were attacked by Alexander the Great, and the repulses which his army, unused to defeat, experienced before he obtained possession of the place; and this he effected only by artifice and treachery. This fortified rock is described as being 25 miles in circumference, and about a mile and a half in height. A narrow path leads to the summit, which is partly arable land, and partly covered with dense woods.

AORTA, the great artery which conveys the blood from the left ventricle of the heart, and by its numerous ramifications distributes it to every part of the body. From its origin in the heart to the arch which it forms when it passes downwards, it is called the *ascending* aorta; and from the arch to the division into the iliac arteries, it is denominated *descending* aorta.

AOSTE, or Aousta, the *Augusta Prætoria* of the ancient Romans, because a colony of 3000 Prætorian soldiers was settled in it by Augustus, in place of the native inhabitants, who were sold as slaves, is a town of Piedmont in Italy, and was formerly the capital of a duchy of the same name; stands on the river Doria, near the foot of the Alps; has a population exceeding 5000; is surrounded with a wall, now greatly decayed; and the remains of an amphitheatre, a triumphal arch erected in honour of Augustus Cæsar, and other vestiges of antiquity, give it a venerable aspect. With the rest of Italy, Aoste fell under the dominion of the French during the revolutionary war. It is 50 miles north-west from Turin.

APACTIS, a genus of plants belonging to the Dodecandria class.

APALACHIAN MOUNTAINS, an elevated ridge which begins at the gulph of Mexico, and stretches northward, nearly parallel to the eastern coast of North America. See Alleghany.

APALACHICOLA, a river of North America, which has its source in the Apalachian mountains; forms the boundary, in one part of its course, between Georgia and West Florida, and, in another, between East and West Florida; and having run nearly 400 miles, discharges its waters into the Mexican gulph.

APAMEA, the name of several ancient cities in Asia Minor, one of which was placed in Bithynia, another in Mesopotamia, and another on an island in the river Tigris; but the most celebrated was called Apamea Cibotos, and stood near the confluence of the Orontes and Marsyas.

A medal struck at this city, in the time of Philip the elder, and hence called the *Apamean medal*, has transmitted its name to modern times, on account of the diversity of opinion and controversy which the device and inscription, equally remarkable, have excited among antiquaries. One side of the medal contains the head of the emperor, adorned with a wreath of laurel, and surrounded with the following inscription in Greek capitals: "The Emperor Cæsar Julius Philip Augustus." The reverse represents a square chest floating in water, the lid is open, and a male and female human figure appear in the inside, and two figures seemingly in the act of devotion. A bird, supposed to have some resemblance to a pigeon, sits on the open lid, and another bird, with a small branch of a tree in its claws, appears flying towards the chest. On the side of the chest itself, and under the male figure, the word *Noe*, also in Greek capitals, is inscribed; from which, and from the device, it is conjectured the medal has a reference to the general deluge, and to the name of Noah. But the reader who wishes to investigate this curious subject may consult Bryant's Mythology, Vol. V. which contains a representation of the medal.

APANAGE, or Appenage, is an appellation of that portion of land which is destined by a sovereign for the support of the younger sons of his family, and which returns to the crown on the failure of the male line of that branch to which it was assigned.

APE, the trivial name of a division of the genus *simia*, which includes the whole tribe of apes and monkeys; the first are distinguished by the want of tails, and the second have long tails. See Mammalia.

APELLES, one of the most celebrated painters of antiquity, was a native of the island of Cos, and flourished about the time of Alexander the Great. Numerous anecdotes are recorded of the graphic skill of this ancient artist; but many of them, it is probable, are the invention of his enthusiastic biographers in succeeding ages. Among others, it is said, that an exquisitely finished picture of Alexander and his horse, did not escape the critical remarks of the conqueror of the world; but a real horse being introduced, was so deceived by the painting that he neighed, and drew from the artist an expression of his opinion, that the horse was a better judge than the king.

The picture of Venus rising from the sea, or, as it is usually denominated, *Venus Anadyomene*, which is described as the most splendid production of his pencil, was painted for his countrymen, and carefully preserved in the temple of Æsculapius, in the island of Cos, was obtained from the inhabitants by Augustus, at the price of a hundred talents of tribute, which he remitted, and was transferred to Rome; but the ravages of time had completed the work of destruction on this precious relic in the reign of the emperor Nero, and a copy, or imitation of the original, was executed and substituted in its place.

APENNINES, a ridge of mountains which branches off from the Swiss Alps, sweeps round the gulph of Genoa, advances eastward to the centre of Italy, and then stretching to the south-east and approaching nearer to the Adriatic than the Mediterranean, terminates in the southern extremity of the Neapolitan territory. Monte Velino, near the middle of Italy, and Cimone, farther to the northward, are the highest mountains of this chain; the latter is 6000 feet, and the former exceeds 7800 feet above the level of the sea.

The mineral productions of the Apennines belong partly to the primary and partly to the secondary class of rocks. Granite, gneiss, micaceous schistus, serpentine, and the celebrated Carrara marble, compose the strata in Tuscany and in the districts contiguous to Genoa; and similar rocks with the famous Sienna marble, and some metallic ores, appear in the territory of Sienna; while a grey limestone, in which petrified organic remains are sparingly embedded, is the prevailing rock in that part of the ridge which lies to the southward of Bologna.

APENZEL, a town and canton of Switzerland. See Appenzel.

APEPSIA, from the Greek, and signifying *want of digestion*, is a synonymous expression with *dyspepsia*, or *difficult* digestion, which is more commonly used by medical writers to denote indigestion, or those symptoms which indicate a deranged state of the stomach and other digestive organs.

APERIENTS, or Aperient Medicines, are such as are supposed to produce the effect of removing obstructions in the glandular or vascular systems of the body. See Materia Medica.

APETALOSE, or Apetalous, a botanical term applied to such flowers as have no petals, of which the flowers of the nettle and *carex*, or sedge-grass, are familiar examples.

APHANES, or Parsley Piert, a genus of plants belonging to the Tetrandria class.

APHEK, the name of several cities mentioned in sacred Scripture; as Aphek in the tribe of Judah, near which the Philistines encamped and took the ark which was brought from Shiloh; Aphek in the valley of Jezreel, which was occupied by the Philistines, while Saul and his army were upon the mountains of Gilboa; Aphek belonging to the tribe of Asher, and near the country of the Sidonians; and Aphek, one of the chief cities of Benhadad's kingdom in Syria, near which the battle between Ahab and Benhadad was fought, and the Syrians being routed, retreated precipitately to the city, and 27,000 were destroyed by the walls which fell upon them. Joshua xv. and xix. 1 Sam. xxix. and 1 Kings xx.

APHELION, from two Greek words, signifying *from the sun*, is that part of the orbit of a planet, which is the most distant from the sun, and is opposed to *perihelion*, or that point of the orbit which is nearest to the sun.

APHIS, the Plant-louse, Vine-fretter, or Puceron, a genus of insects belonging to the order Hemiptera, and including numerous species, which latter derive their characteristic appellations from the plants of which they are inhabitants. More than 70 species have been described; and the natural history of the whole tribe has been long a subject of curious investigation. See Entomology.

APHORISM, from the Greek, and signifying to *separate*, a sententious expression, containing a maxim or principle of a science, as, in medicine, the *aphorisms* of Hippocrates, of Boerhaave, &c. and *aphorisms* of civil law, &c.

APHRODISIA, festivals instituted in honour of Venus in different parts of Greece, the most splendid of which were celebrated in the island of Cyprus.

APHRODITA, a genus of marine animals belonging to the class of Vermes, several species of which are natives of the British shores. *Aphrodita aculcata*, or sea-mouse, is remarkable for the beautiful iridescence of the hairy appendages which are the instruments of locomotion, and seem to supply the place of feet.

APHTHÆ, from the Greek, signifying *to inflame*, a disease of the mouth in which small superficial ulcers appear. See MEDICINE.

APHYLLANTHES, Leafless Flower, as the word imports, or blue Montpelier pine, a genus of plants belonging to the Hexandria class.

APHYTEIA, a genus of plants belonging to the Monadelphia class, formed from the only species yet known, *Hydnora*, which is a native of the Cape of Good Hope.

APIARY, a place where bees are kept. For an account of the economy and management of those insects,—see BEE.

APICIUS, seems to have been a general appellation for a glutton, or rather epicure, among the Romans; at least the celebrity of three persons of the same name, who lived at different periods, is recorded. The most famous of this group of epicures lived in the time of Tiberius, and was possessed of immense wealth. In obtaining the choicest, the rarest, and most expensive dishes, among which are enumerated some entirely composed of the tongues of nightingales and peacocks, to gratify the luxury and caprice of a depraved appetite, he expended more than L.800,000 Sterling; and finding that his fortune was diminished, by this wanton expenditure, to L.80,000 Sterling, another depraved feeling seized his mind. The dread of starvation threw him into despair; he swallowed a poisonous draught, and thus miserably terminated an inglorious life.

APIS, the bee, a genus of insects belonging to the order Hymenoptera, and including nearly 300 species, of which more than a hundred are natives of Britain. For the characters and classification, see ENTOMOLOGY; and for the economical history and management of the domestic bee, see BEE.

APIS, the sacred bull of the Egyptians, which was an object of veneration as the representative of Osiris. The bull, from its utility in the labours of the field, was consecrated to Osiris, who was the inventor of husbandry; or, according to the doctrine of transmigration, the soul of Osiris passed into that animal, and hence it became a symbolical deity, and at last a real object of worship.

The mythological history of the sacred bull traces his origin to the influence of lightning, and assigns certain external marks as the real characteristics of his divinity. A white square spot on the forehead, a white crescent on the right side, the figure of an eagle on the back, the rest of the body jet black, and a knot like a beetle under the tongue, were considered the true signs of the animal that was destined to receive divine honours; and when a bull with these indications appeared, the discovery was announced to the people; solemn festivals were instituted at his installation; an annual celebration of seven days was appointed and observed throughout the kingdom; the deified animal was attended by a numerous train of priests; was consulted as an oracle, and the prediction of future events was pronounced favourable or adverse to the person from whom he received or rejected proffered food. Twenty-five years were fixed as the utmost period of his existence; and if he survived that period, he was drowned in the fountain of the priests. His death produced universal despair; but when another divinity was found and announced, grief and lamentation were succeeded by exultation and joy.

The worship of Apis, or the veneration paid to the sacred bull, it has been alleged, with some degree of probability, has some reference to Astronomy; Apis was the tutelar divinity of the new form of the solar year, and the time prescribed for his life corresponds with a period of the sun and moon. In the mythology of this emblematical deity, some allusion is made to a presiding power over the inundation of the Nile, an event on which the fertility of the soil, and the abundance of the fruits of the earth, essentially depend in Egypt. The idolatrous worship of the golden calf, into which the Israelites fell, is supposed to be derived from this Egyptian superstition.

APIUM, or PARSLEY, a genus of plants belonging to the Pentandria class, and to the natural order of umbellated plants.

APLUDA, a genus of plants belonging to the Polygamia class, the species of which are natives of America and the East Indies.

APLYSIA, or LAPLYSIA, a genus of animals belonging to the order Mollusca, under the class Vermes. See HELMINTHOLOGY.

APOCALYPSE, or the REVELATION, one of the sacred books of the New Testament, which is understood to contain predictions concerning future events in the condition of the Christian church. It was written, according to some commentators, about the 96th year of Christ, in the island of Patmos, to which place St John the Evangelist, or the Divine as he is called, was banished by the emperor Domitian. But others assign to it an earlier date, and some ascribe it to a different author. The authenticity of the book of Revelations has not been always acknowledged; and, among others, it was excluded by Luther from the canonical books of sacred Scripture. But it was admitted by the principal fathers of the church in the fourth and fifth centuries, and continues to hold the same place in protestant churches.

APOCOPE, a figure in grammar, by which a letter or syllable is cut off from the end of a word, as *ingenî*, for *ingenii*, *dic* for *dice*.

APOCRYPHA, from the Greek, signifying *concealed* or *obscure*, is the name of such books as are rejected from the canon of Scripture by most churches, because they are of obscure or doubtful authority. It is supposed, that the books to which the denomination *Apocryphal* is now applied, were not considered authentic by the Jews; they are not alluded to by the writers of the New Testament; and they were not admitted into the canonical scriptures of the Christian church in the early period of its history. Some part of the apocryphal books is received by the church of Rome; the church of England recommends them to be read as examples of life and instruction of manners; but they are altogether rejected by the church of Scotland. See Prideaux's *Connections*.

APOCYNUM, or Dogsbane, a genus of plants belonging to the Pentandria class.

APODES, signifying *without feet*, is the first order in the class of fishes according to the Linnæan arrangement, and is thus characterised because the fishes included in it are destitute of ventral fins. See Ichthyology.

APOGEE, signifying *from the earth*, denotes that point in the orbit of a planet which is most distant from the earth.

APOLLINARIAN GAMES were instituted at Rome in honour of Apollo, and were at first celebrated only occasionally, according to the pleasure of the prætor; but about 542 years from the building of the city, a law was passed, appointing an annual celebration on a certain fixed day, which was on the 5th of July. Singing and instrumental music were originally the principal part of the entertainment; but dancing, and other performances, were afterwards introduced, and the spectators were decorated with crowns of laurel.

APOLLINOPOLIS, Great and Small, the ancient name of two celebrated cities in Egypt, now called *Etfou* and *Kous*, which are only miserable villages, exhibiting a melancholy contrast with the magnificent remains of their former splendour, which are still visible. See Denon's *Travels*, vol. iii.

APOLLO, the most celebrated of the heathen deities among the Greeks and Romans. Four divinities of the same name are noticed by Cicero; but the Apollo who is described in mythological history as the son of Jupiter and Latona was the most famous, and always received the most distinguished honours. The name of Apollo is derived, according to one etymology, from the Greek, signifying *the Destroyer*, and according to another *the Deliverer;* but his epithets, expressive of his influence and attributes, are numerous. He is called *Pythius*, either because he slew the serpent Python, or because he is the god of augury; *Pæan*, from the word to strike, because he is the god of archery; *Phœbus*, or the *light of life; Phanæus*, from his splendour; *Delius*, from the island Delos, his birth-place; *Cynthius*, from a mountain in the same island; and *Nomius*, or the Shepherd, from the fertility and enlivening influence which he communicates to the earth.

Divine honours were paid to Apollo as the god of poetry and music, of medicine, augury, and archery. He is represented as a beautiful youth, with a bow and arrows in his right hand, and in his left a harp or lyre; and he is considered a symbolical deity, of whom the sun is the great antitype. Ancient mythology describes him as the son of Jupiter, because that god is the author of the world; his mother was called *Latona*, signifying *hidden*, because before the creation of the sun all things were wrapped up in the darkness of chaos; he is always in the bloom of youth, because the sun grows not old; the bow and arrows imply the piercing solar rays; and the ceremonies of his worship had an obvious reference to the great source of light of which he is the representation.

Youth and beauty
Eternal deck his cheek; from his fair head
Perfumes distil their sweets; and cheerful health,
His duteous handmaid, through the air improv'd,
With lavish hand, diffuses scents ambrosial.
The spearman's arm, by thee, great god! directed,
Sends forth a certain wound. The laurel'd bard,
Inspired by thee, composes verse immortal.
Taught by thy art divine, the sage physician
Eludes the urn, and chains or exiles death.

Prior.

APOLLO BELVIDERE, one of the most celebrated statues of antiquity, shone conspicuous among the noble monuments of art which adorned the halls of the Louvre at Paris, but is now restored to its native soil.

APOLLONIUS, of Perga, a city of Pamphylia, was one of the most distinguished of the ancient mathematicians, flourished about 200 years before the Christian era, and by his profound investigations merited and obtained the noble appellation of the *Great Geometer*. He studied at Alexandria under the disciples of Euclid, and wrote various works on the subjects of his studies; but a Treatise on Conic Sections is the only monument of his genius which time or accident has spared, and of this work, which was composed in eight books, seven have been preserved, four in the original Greek, and three in Arabic translations. A splendid edition of this work was published by Dr Halley at Oxford in 1710.

APOLLYON, or, *the Destroyer*, is mentioned in the book of the Revelations, and corresponds with the Hebrew Abaddon. See Abaddon.

APOLOGUE, a moral fable, or fictitious narrative, which is intended as an agreeable and impressive method of communicating useful instruction. In the parable, the incidents are drawn from what passes in real life among mankind, and the narration must be clothed with probability; but the apologue is not restricted to the rigid rules of probability; the actions of inferior animals, and even of inanimate objects, are introduced. This mode of writing is common in eastern countries; and the fables of Æsop are a familiar example.

APONEUROSIS, a tendinous expansion which stretches over the muscles, and which seems to be intended to facilitate their action; was supposed by the ancient anatomists to be derived from the nerves, and hence the name.

APONO, Peter D', or Abano, a physician and philosopher of the 13th century. See Abano.

APONOGETON, a genus of plants belonging to the Dodecandria class.

APOPHYSIS, an anatomical term for those processes of bones which grow from the bone itself, as the word imports, and are not attached by cartilages.

APOPLEXY, a disease in which the patient is deprived of sensation and voluntary motion. See MEDICINE.

APOSTLE, in its original sense, signifies a messenger sent by another on some particular business, and it is the usual appellation of the twelve disciples, who were commissioned by Jesus Christ to preach the gospel. Twelve apostles were chosen, it is supposed, in allusion to the twelve patriarchs, or to the twelve chief heads, or rulers of the tribes of Israel. The first commission which the apostles received from Christ in the third year of his ministry, limited their labours to the Jewish nation. They were sent out two and two; and in obedience to the command of their Lord, they visited all parts of Palestine, preaching the gospel and working miracles. Their second commission, which was delivered before our Lord's ascension, empowered them to preach the gospel to all nations. Having exercised their ministry for 12 years in Judea, they resolved to disperse to different parts of the world, and determined by lot what country should be assigned to each. According to this arrangement, Peter and John went to Pontus, Galatia, and some other provinces of Lesser Asia; St Andrew to the northern country of Scythia; St Philip to Upper Asia, and some parts of Scythia; St Bartholomew to Arabia; St Matthew to Chaldea, Persia, and Parthia; St Thomas to different parts of India; St James the less remained in Jerusalem, and became bishop of that church; St Simon went to Egypt, Cyrene, Libya, and Mauritania; St Jude to Syria and Mesopotamia; and St Matthias, who was chosen in the room of Judas, to Cappadocia and Colchis. Two apostles, Paul and Barnabas, were added to the original number; and the former is called, by way of eminence, *the Apostle*, and sometimes *the Apostle of the Gentiles*, because, through his ministry, the conversion of the gentile world was chiefly accomplished.

In representations, or paintings, the apostles are distinguished by peculiar badges, or attributes; St Peter is painted with the keys; St Paul with a sword; St Andrew with a cross; St James the greater, with a pilgrim's staff and a gourd bottle; St James the less, with a fuller's pole; St John with a cup, and winged serpent flying from it; St Bartholomew with a knife; St Philip with a long staff, whose upper end is shaped like a cross; St Thomas with a lance; St Matthew with a hatchet; St Matthias with a battle axe; St Simon with a saw; and St Jude with a club.

APOSTROPHE, from the Greek, and signifies *turning away*, is a figure in rhetoric by which those who are absent or dead are addressed as if they were present, and in this way the speaker turns away his discourse from the audience before him. This figure of speech, which is the natural expression of strong emotion, and is chiefly employed by orators and poets, is closely allied to personification, which is also the effect of strong feeling, which addresses itself even to the inanimate objects of nature. The apostrophe was much employed by the celebrated orators of antiquity. The address of Demosthenes to the Greeks who fell in the field of Marathon, is a fine example of this figure. In the oration for Ligarius, the address of Cicero to Tubero is not less splendid, and has been always regarded as one of the most beautiful passages in the works of the Roman orator; and in his oration for Balbus, he thus apostrophizes inanimate nature to bear witness to the virtues of Pompey: "I invoke you, mute regions; you most distant countries; you seas, havens, islands, and shores; For what coast, what land, what place is there, in which the marks of his courage, humanity, wisdom, and prudence are not visible?" Such figures are not unusual in sacred Scripture; thus, "Hear, O heavens! and give ear, O earth! for the Lord hath spoken;" and, "Be astonished, O ye heavens! at this."

APOTHECARY, a person who practises the art of pharmacy, who sells drugs employed in medicine, and prepares them according to the prescriptions of physicians. The apothecaries of London, who constitute one of the city companies, were incorporated by royal charter in the time of James I. by which, and subsequent enactments, they are entitled to certain privileges. They are obliged to make up their medicines according to the directions of the College Dispensatory; and their shops are subjected to visitations by the censors of the Royal College of Physicians, who are empowered to destroy all medicines of a bad quality. Those who wish to trace the history of the establishment of apothecaries in different countries, may consult Beckmann's *History of Inventions*, Vol. II.

APOTHEOSIS, or deification, the ceremony of consecrating heroes and great men after death, observed among the ancients, by which they were enrolled among the gods. Temples and altars were erected to their honour, priests were appointed, and a system of worship was instituted. The form of apotheosis was the following: The body of the deceased for whom this honour was destined was burnt with the usual solemnities; an image of wax, having an exact resemblance, was placed on an ivory couch, where it lay in state for seven days, attended by the senate and ladies of the highest rank, in mourning. The young senators and knights then bore the couch through the Sacred Way to the Old Forum, and afterwards to the Campus Martius, and placed it on an edifice constructed in a pyramidal form. Combustible matters and aromatic substances were strewed around the couch; the knights walked round the pile in solemn procession, and the new emperor set fire to it with a torch; while an eagle with a firebrand, mounting in the air from the summit of the pile, was supposed to carry the soul of the new divinity to heaven.

APPARENT, a term used by astronomers, and expressive of the appearance of the heavenly bodies, as, the apparent distance or magnitude of the sun or planets, in opposition to the real distance or magnitude as they are ascertained by observation and calculation.

APPARENT HEIRS, a term in law, denoting those whose right of inheritance is undoubted and fixed, provided they survive the ancestor or possessor, as the eldest son, or his offspring, who, by the course of common law, are heirs to the father at his decease.

APPARITION, in its general meaning, denotes simply the appearance of an object, but in its more restricted sense it signifies the preternatural appearance of departed spirits. Such preternatural appearances are recorded both in sacred and profane history. Samuel, who was raised by the witch of Endor, is mentioned in the Old Testament; and the appearance of our Saviour, after his crucifixion, to some of his disciples, and of the angel to the apostle Peter in prison, is detailed in the New Testament. The apparition which presented itself twice to Brutus, the first time before he left Asia, and again on the night before the battle of Philippi, is one of the most remarkable examples in ancient history. A similar apparition is noticed by Clarendon, in his history of England; it was the apparition of Sir George Villiers, the father of the duke of Buckingham, which was seen by an officer, and warned him of the assassination of the duke.

Of the preternatural appearances, or apparitions, which are recorded in Scripture History, it has been generally admitted that they ought to be regarded as deviations from the ordinary course of nature, which are permitted for the accomplishment of some useful purpose, or the communication, or confirmation, of some important instruction or essential doctrine. But the existence of other apparitions is usually ascribed to delusions of the imagination, or to lively impressions produced in the mind by those objects which excite deep interest, and strong emotions. In this way the apparition of Sir George Villiers is accounted for. The indignation against the duke of Buckingham had become general, and the dread of assasination had taken strong hold of those whose fortune or expectations were connected with the life of that royal favourite. The officer who saw the apparition was perhaps one of those whose minds were agitated with conflicting passions, in the fear of that event. The father of the duke, who might be supposed, by no great effort of imagination, to be in life, or even his unembodied spirit, could not contemplate with indifference the approaching fate of his son; and, in the perturbation of thought which filled the mind of the officer, he seemed to appear to his alarmed apprehension, to warn him of the impending blow.

APPARITOR, a general appellation applied to all the attendants of the Roman judges and magistrates who were appointed to receive and execute their orders; but in modern times it is restricted to the messenger, or officer, of an ecclesiastical court, or to the beadle of a university, who carries the mace.

APPEAL, a law term, which denotes the removal of a cause from an inferior court to a superior tribunal. In ecclesiastical cases in England, the right of appeal lies from the archdeacon's court to the consistory court of the diocesan bishop, and from this latter to the archbishop of each province, or the court of arches, and, last of all, to the king in chancery, as the head of the church. In civil cases, appeals lie from all the inferior courts in England, as well as from the equity courts of chancery, to the House of Lords. See *Blackstone's Commentaries.*

In matters connected with the church in Scotland, appeals lie from the kirk-session of each parish to the presbytery, from the presbytery to the synod, and, lastly, to the General Assembly, whose judgments are final. In civil causes in Scotland, appeals lie from all the inferior courts to the Court of Session, and from the Court of Session to the House of Lords. Appeals also lie from the inferior courts in Scotland to the circuit, or criminal court of the district, in certain criminal cases, and in civil cases where the subject in question exceeds not twelve pounds sterling. Appeals are brought from the inferior courts to the Court of Session by *advocation*, *reduction*, or *suspension*. See *Appeal*, in *Bell's Dictionary of the Law of Scotland.*

APPEAL, also a term in English law, denotes a criminal prosecution, at the instance of a private individual, to obtain the award of punishment on account of a particular injury, rather than in the view of an offence against the public, and, in this sense, corresponds with the *accusation* of civilians. This mode of prosecution, which seems to have had its origin in those times when compensation was made for offences by the payment of money to the injured person, is still in force, but rarely resorted to; and even at this day, according to the Turkish criminal code, murder is regarded as a private injury, and is prosecuted by the relations of the deceased. See *Blackstone's Commentaries.*

APPELLATION, the name by which any object is distinguished or known. Singular corruptions of names have arisen, from ignorance either of the language from which they are derived, of the manners and customs in which they originated, or the changes to which they have been subjected. Some of these corruptions are not a little ludicrous. The *O yes* of the crier of courts of justice, is a corruption of the French verb *oyez*, *hear ye*, or *listen*; *Beef-eaters*, applied to the yeomen of the royal guard, is derived from *Buffetiers*, because, on great solemnities, they waited at table, or attended at the *buffet*; *Blanc Nez*, or White Headland, has been transformed into *Blackness*; and *L'Aiguille et Fil*, the Needle and Thread, by mis-spelling has been changed into *L'Aigle et Fils*, and being literally translated *Eagle and Child*, has given origin to a common sign.

The capture of the town of Boulogne, in the time of Henry VIII. was a popular event, and gave birth to two signs, which, under various changes, have been transmitted to the present day, but altogether unlike the original prototype. The port, or harbour of Boulogne, was the sign of a well-known inn in Holborn, in London, which was distinguished by the appellation of the *Boulogne Mouth;* but its origin was forgotten, and, from the corruption of the name, a new edition of the sign appeared, and exhibited a *bull* and a gaping *human mouth*, and, under the title of the *Bull and Mouth*, is recognised at this day. The sign of the *Bull and Gate* acknowledges a similar origin. The gates of Boulogne at the same time being transported from France, and deposited at Hardes in Kent, as a monument of the victory, became also a popular sign, under the appellation of *Boulogne gate*, which was afterwards converted into the *Bull and Gate*. The sign of the *Bell and Savage*, or, as it is familiarly called, *Bell Savage Inn*, is supposed to be derived from *La Bell Sauvage*, the beautiful savage, alluding to a female found in the woods in France, or from Lady Arabella Savage, to whom the property originally belonged. The sign representing a *bell* and *a wild man*, is conjectured to have been intended as a rebus for her name.

APPELLATIVE NAMES, are such as are applied to a class of objects, as *city*, *river*, *man*, *bird*, in opposition to proper names, which are limited to a single object.

APPENRADE, or ABENRADE, a town of the duchy of Sleswick, in South Jutland, in Denmark, stands on a bay of the Baltic, and is four miles distant from Flensbourg; the surrounding hills protect the harbour, which is commodious, from storms; the trade is considerable, and ship-building is extensive; its commercial prosperity has greatly increased the number of the inhabitants.

APPENZEL, a canton of Switzerland, about thirty miles in length and twenty miles in breadth, is a mountainous district, but affords good pasture, and yields some grain and fruits. The population exceeds 50,000, of whom 13,000 are Roman catholics. Some linen, crape, fustian, and thread are manufactured.

APPENZEL, a town of Switzerland, and capital of the canton of the same name, stands on the banks of the river Chus, is forty miles east from Zurich, and in N. Lat. 47° 17'. and E. Long. 9° 31'.

APPETITE, in its general signification, is the desire or inclination which is supposed to be conducive to our happiness. Writers on morals have divided appetites into sensitive and rational. Under the first are included those which proceed from the impulse of the senses, or from a blind propensity to a certain object, and are not subjected to the influence of reason; but the rational appetites originate from reflection on the intrinsic value of the object, and thus are under the guidance of reason. The word appetite is properly limited in its application by Dr Reid to that class of desires which are accompanied with an uneasy sensation, and which are strong or weak in proportion to the desire of their proper objects, which are not constant, but, being sated by their objects for a time, return after certain periods. Of such desires, or appetites, hunger and thirst are examples.

APPIAN, an eminent Roman historian, who was a native of Alexandria, flourished about the beginning of the second century, in the time of Adrian, Trajan, and Antoninus Pius, and became celebrated as a pleader at Rome. His History of the Roman Empire is composed in the Greek language, and is included in twenty-four books, fragments of some of which only are extant; but the narrative is generally regarded as authentic, the stile is simple, and the work displays great knowledge of military affairs.

APPLAUSE denotes the approbation of an audience at a public spectacle, which is expressed by the clapping of the hands. See ACCLAMATION.

APPLEBY, the county town of Westmoreland, in England, stands on the banks of the river Eden, was a Roman station, and at one period of its history enjoyed great privileges and prosperity. It is now chiefly distinguished by an abundant corn market. The population scarcely exceeds 800, and it is 29 miles distant from Carlisle.

APPOGIATURA, from a word which signifies to lean upon, is a small additional note introduced between two other notes, for the purpose of embellishment in musical compositions.

APPRENTICE, from the French word which signifies *to learn*, denotes a person who is engaged to serve a master for a fixed period, for the purpose of being instructed in some art or profession. Various regulations, with regard to the obligations under which masters and apprentices bind themselves, and with regard to the privileges and immunities which belong to those who have served a legal apprenticeship, have been enacted by the legislature from the time of Queen Elizabeth down to the present day.

APPRENTICESHIP, the period of service during which an apprentice, by the contract he has entered into, is bound to remain with a master, for the purpose of learning an art or profession. The nature and mutual obligations of engagements of this kind, hold a conspicuous place in the modern code; but as such contracts are passed over in silence in the Roman law, and even no word in Greek or Latin expressive of such a connexion, it is supposed that they were unknown in ancient times. Is it not probable that those arts and trades for which apprenticeships are thought necessary in modern times, were exercised by slaves among the Greeks and Romans, and in this way were overlooked in their political regulations?

The duration of apprenticeships is different in different towns and trades in France. In many trades five years is the usual term in Paris. The act of the legislature passed in the fifth year of Queen Elizabeth's reign, and called the *Statute of Apprenticeships*, fixes the period at seven years; and this became the public law in all arts and trades practised in market towns; but its operation is understood to be limited to those trades which existed when the enactment was made. No general law has prevailed in Scotland to regulate the term of apprenticeship. The period is therefore different in different corporations, and rarely exceeds three or five years. The restrictions relative to apprenticeships in Ireland are similar to those of England; but by a regulation of the Irish government, which was ratified by a legislative enactment in the reign of Charles II., foreigners and aliens are admitted freemen in any city or corporation, on payment of the small fine of twenty shillings to the municipal authorities.

The necessity and inconveniences of apprenticeships have been a subject of controversy among writers on political economy. Apprenticeships are necessary, it is alleged, to give sufficient time to those who are to be employed in any art or trade to acquire habits of industry, and at the same time to insure to the public perfect workmanship in the productions of any trade or manufacture. But, on the other hand, it is maintained, that the apprentice receiving no wages is a loser, and the master a gainer by the fruits of his labour, in a very disproportionate degree; and the loss sustained by the one and the gain of the other, increase in proportion to the length of the period of service. It is supposed also that apprenticeships are injurious to the public, by excluding competition, and thus preventing the productions of art from being brought to market at the lowest possible price. But the evils which arise from corporation laws, when rightly investigated, may perhaps appear to be more imaginary than real; the expedients resorted to for relief often obviate their effects; and in England the more oppressive restrictions were removed, in 1813, by a repeal of parts of the statute of Elizabeth.

APPRISING, an action in the law practice of Scotland, by which a creditor attached the estate or property of a debtor for payment of a debt, which property was redeemable by the debtor within a prescribed period. This form of diligence is now disused, and the mode by adjudication substituted in its place.

APPROACHES, a term used in fortification, to denote the works which are thrown up by besiegers to enable them to approach nearer a fortress without being exposed to the guns of the enemy.

APPROACHING, a method of engrafting a shoot of one tree on a branch of another, without removing it from the parent stem till the union be completed.

APPROBATION, a term used by writers on morals, and expressive of the satisfaction which is felt in the contemplation of certain actions. The principle of approbation is ascribed by some to the feeling of self-interest, and by others to motives of pure benevolence, altogether independent of private happiness.

APPROPRIATION, a term in English law, which denotes the separation of a benefice, and its perpetual annexation to some religious corporation. When the parochial clergy were first instituted, the tythes were divided into four parts; one part was destined for the bishop, one for defraying the expence of repairs of the church, a third for the poor, and a fourth as a provision for the incumbent. When the bishops were otherwise provided for, they were excluded from their share of the tythes, which were then distributed into three parts only. The monasteries devoted a small portion to the support of the officiating priest, and reserved the remainder to the pious uses of their own institutions. All the advowsons within their reach were obtained by gift or purchase, and the benefices were appropriated to their own corporations. To complete such appropriation, the king's licence in chancery must be obtained, and the consent of the patron and incumbent when the church is full, and of the diocesan and patron when the benefice is void. See *Blackstone's Commentaries.*

APPROXIMATION, a term in arithmetic and algebra, which denotes the nearer and nearer approach to a root or other quantity sought, without finding it exactly.

APPULSE, denotes the approach of a planet to a conjunction with the sun or a star. Some astronomers employ this term to express the apparent contact of the two bodies; and by others it is considered synonimous with *occultation*, when one of the bodies is completely obscured by the other.

APRIL, derived from the word *aperio*, "to open," is the fourth month of the year, according to the common computation; and is thus denominated from the opening or expansion of the buds, or, in a more extended signification, because the earth in this season opens her bosom for the production of vegetables.

APSIS, a term in astronomy, denoting the two points of a planet's orbit, when it is at the greatest and least distance from the sun or earth. The line connecting these points is called the *line of the apsides*. The *higher* apsis is the point nearest the sun or earth, and corresponds with perihelion or perigee; and the *lower* apsis, which is analagous to aphelion, or apogee, is the point most distant from the sun or earth.

APTERA, from the Greek, and signifying *without wings*, is the seventh order in the Linnæan classification of insects, and, as the name imports, includes those insects which are destitute of wings. See Entomology.

APULEIUS LUCIUS, a Roman philosopher, who professed to be a disciple of the Platonic sect, but is chiefly celebrated as the author of a singular romance under the title of the *Golden Ass*, was a native of a Roman colony in Africa; flourished in the second century under the Antonines; studied at Carthage, Athens, and Rome, and in a short time became so perfect in the Latin language that he acquired great reputation as a public pleader. He was charged with using magical incantations in obtaining a rich widow in marriage; and it is supposed that the accusation may have originated either in his own belief in the art of magic, or from the remarkable adventures detailed in the Golden Ass, many of which are accomplished by means of that occult science; but it is more probable that it arose from the prevailing notions of the times. In the work alluded to, which is considered as the original of all succeeding romances, the author is introduced ingratiating himself into the confidence of the female servant of a sorceress, from whom he acquires the secrets of the art of her mistress. Anxious to possess the means of extending his knowledge, he expressed a wish to be transformed into a bird; but the wrong ointment being applied, effected his transformation into the form of an *ass;* in this form he is seized by robbers, loaded with their booty, and conducted to a cave, the scenery of which, the inhabitants, and the incidents that occurred during his residence in it, have a near resemblance to the description of the cave of the robbers in the celebrated Gil Blas of Le Sage; and having encountered many other adventures, he is at last restored to his own proper form.

APYROUS, a term which is equivalent with incombustible, is applied to those substances which remain unchanged in the strongest heat.

AQUA FORTIS, or the common nitric acid of the shops, in that degree of dilution which is necessary for many purposes in the arts.

AQUA REGIA, a compound of nitric and muriatic acids, was so denominated by the alchemists and older chemists, because it dissolves gold, the *king* of the metals. See Chemistry.

AQUA TOFANA, a poisonous liquid, which is said to have been extensively employed at Naples and Rome during the latter half of the 17th century, and has been the subject of some very learned dissertations to prove its existence and effects. Six hundred persons, according to the pretended confession of the inventress, Tofania, are said to have fallen victims to this secret poison. But the whole story forms such a tissue of improbabilities, absurdities, and contradictions, that a sober enquirer would be almost disposed to doubt the whole. Of the infamous Tofania herself, it is said, that "the little that we know of her rests upon the authority of travellers, and is evidently exaggerated, and sometimes irreconcileable with established facts." One traveller asserts, that Tofania was dragged from a sanctuary by the civil power, and after being strangled, her body was thrown at night into the court of the convent, for the purpose of suppressing the indignation of the clergy on account of the violation of the sanctuary. But at the distance of 15 and 20 years, two other travellers declare that she was alive and in prison. It is stated by one author, who visited Naples in 1780, that this poisonous liquor was still in use, while another regards it as an unfounded calumny.

The nature and effects of this liquid exhibit the most extraordinary part of its improbable history. It is described "as being as limpid as rock-water, and without taste;" and there was not a lady in Naples who had not some of it lying openly on her toilette among her perfumes. "It was generally believed that the effect of this poison was certain death;" and that it could be so managed as to prove fatal in any determinate time, from a few days to a year or upwards. Four or six drops were reckoned a sufficient dose, and they were said to produce no violent symptoms, or but very seldom; no pains, convulsions, inflammation, or fever, but only a feeling of indisposition, without any very definite symptoms, except, sometimes, inextinguishable thirst. The victim, however, sunk into a languid state; and with disgust at food, and weariness of life, death closed the scene. It was at last discovered, that lemon-juice, early and copiously administered, was sometimes a certain antidote, and brought the poison into disrepute.

That crimes of so deep a dye exist among a dissolute and licentious people, as well as among nations more distinguished by morality and humanity, can scarcely be doubted; but that they prevailed to such extent, and were perpetrated by means of a liquid "as limpid as rock-water, and without taste," and with a few drops of this liquid, which had no perceptible effects on the unfortunate victims, and could be so managed as to produce certain death at the end of a few days, or at the end of twelvemonths, exceeds all power of belief. The whole story must either be regarded as a mere fiction, invented for the amusement of the credulous, or it may be traced to an aberration of the mental faculties, somewhat akin to the notion of witchcraft, which had taken a strong hold of the minds of the inhabitants of the northern part of this kingdom about the same period, and spread so rapidly in New England as to threaten the depopulation of that infant colony. See Beckmann's *History of Inventions*, and *Aqua Tofana in Supplement to Encyclopædia Britannica*.

AQUA VITÆ, or water of life, spirits obtained from vegetable productions by means of fermentation and distillation. The spirits from the fermented juice of the grape are well known by the name of *brandy*, and from grain by the denomination of *whisky*, in Scotland. To the latter production the term *aqua vitæ* is restricted by some.

AQUÆ, along with some descriptive appellation, is applied to many places which were formerly under the dominion of the ancient Romans, and were usually places of resort on account of mineral waters; as *Aquæ Calidæ*, from its hot springs, now Bath, in England; *Aquæ Calidæ*, for the same reason, now Orense, in Spain; and *Aquæ Sextiæ*, a colony founded by Sextius Calvinus, contiguous to a spot abounding in cold and hot springs, and now Aix in France.

AQUÆDUCT, an artificial structure for conveying water over an unequal surface. Unacquainted with the hydraulic principle of water that is conveyed in pipes to whatever depth they are laid below the level always rising to the height of its source, the ancients supplied their cities with that necessary fluid, by conducting it nearly on a level, or at least with a gentle slope to produce a current towards the place of discharge; and when the inequality of surface over which the water was to be carried, did not admit of such a conveyance, an artificial course was formed, by perforating mountains, and raising ranges of arches in vallies. The stupendous works of the Romans, which were constructed for this purpose in different parts of their extensive empire, still excite, in their magnificent and mouldering remains, the wonder and admiration of succeeding ages. The arches were constructed of stone or brick, and when the valley was deep, several ranges of arches, one above another, were formed. Some of the arcades of a Roman aquæduct, which conveyed a large body of water across the Moselle, are still visible near Metz; and 159 arches composed of massy stones, joined without mortar, yet exist a striking monument of Roman grandeur at Segovia in Spain. In this aquæduct a double range of arches raised the water to more than 100 feet.

The most splendid aquæduct of modern times was constructed by Louis the XIV. of France, for conveying the waters of a river to Versailles. It consists of 242 arches arranged in three rows, and the length of the course is 7000 fathoms. In Britain such structures are usually destined for conveying the waters of canals across vallies. A magnificent aquæduct carries the Ellesmere canal over the vale of Llangollen in North Wales; and the vale of the Kelvin five miles from Glasgow is traversed by an aquæduct on a smaller scale for continuing the course of the Forth and Clyde canal.

AQUAMBOE, or AKAMBO, a kingdom on the coast of Guinea, in Africa, which occupies only about 20 miles of the coast, but extends more than 100 miles inland. The natives are described as a warlike race, divided into tribes, which are subject to the king of Aquamboe, whose authority is stated to be highly tyrannical and oppressive. With a soil generally fertile, the produce of their agricultural labours secures them not always from a scarcity, and their trade is of no great account.

AQUARIUS, or the water-carrier, is the eleventh sign of the zodiac, through which the sun moves in the month of January.

AQUARTIA, a genus of plants belonging to the Tetrandria class.

AQUATINTA, a method of engraving on copper, from which soft and beautiful impressions, resembling drawings with Indian ink, are obtained. See ENGRAVING.

AQUILA, a constellation of the northern hemisphere which is generally united with Antinsus, and includes, according to the Britannic catalogue, 71 stars.

AQUILA, a town of Naples, and capital of farther Abruzzo, contains 10,000 inhabitants. The culture of saffron in the neighbourhood was formerly extensive. This town suffered a dreadful calamity from an earthquake in February 1703. On the first shock the inhabitants fled from the city, but returned to vespers in the evening, when the shocks were repeated, and 24,000 persons were buried in the ruins, 1500 were wounded, and a church with 800 persons, who had fled to it for shelter, was swallowed up. Aquila is 30 miles distant from the sea.

AQUILEGIA, or COLUMBINE, a genus of plants belonging to the Polyandria class.

AQUILEIA, once a flourishing and populous city of Italy, has now dwindled to a small village. It stands at the entrance of the gulf of Trieste. In the fifth century it resisted a siege of three months, but at last was forced to yield to the victorious arms of Attila king of the Huns.

AQUINAS, THOMAS, a scholastic divine of the 13th century was born at Aquino, in Italy, from which he derives his name, in 1224, and died in 1274, is greatly celebrated for his profound studies and voluminous writings, to which high authority is attached in the Roman Catholic church. He was canonized in 1323, by the Pope; and, in the 16th century, Pius V. distinguished him by the honourable appellation of the fifth doctor of the church.

AQUITANIA, an ancient province of Transalpine Gaul, which was conquered by Cæsar and his lieutenants, was, after various revolutions, erected into a kingdom by Charlemagne, in the 8th century, but was reduced to the rank of a dukedom by Charles the Bald. The wealth and effeminate manners of the Aquitani rendered them an easy prey to the warlike Romans. Guienne and Gascony are supposed to include this province.

ARABESQUE, or MORESQUE, a style of ornamental painting and sculpture, which was practised by the Arabs and Moors, for the decoration of their apartments; the origin of which, it is said, is derived from the prohibition of the use of images of men or other animals, by the Mahometan religion. Imaginary plants, stems, and foliage, are substituted in their place.

ARABIA, a large country in Asia, is distinctly bounded by the Red sea on the west, the Indian ocean on the south, the Persian gulf and the Euphrates, or more correctly speaking, the deserts towards the west of that river, on the east; while the northern limit, which is much less obvious, may be said to be determined by Palestine and Syria, or the bleak and almost uninhabitable country which extends from the isthmus of Suez to Palmyra, and the same river, forming part of the modern Pachalic of Damascus. Its length, from Cape Babelmandel, at the entrance of the Red sea, to the north-east extremity on the Euphrates, is estimated at from 1500 to 1800 British miles, and its breadth, in the direction of the tropic of Cancer, at about 800; so that, in general terms, this country may be conceived to be nearly four times larger than the kingdom of France, according to its ancient and restricted dimensions.

Divisions.—This extensive region, from the time of Ptolemy the geographer, has been divided into three unequal portions, the names of which, though not recognized by the natives, are very characteristic of some striking peculiarities. Thus, Arabia Petræa, or the Stoney, designates a small country in the north-west corner, adjoining the Red sea, Egypt, and Palestine, remarkable for the abundance of rocks and hills; Arabia Deserta is the significant term appropriated to an immense sandy plain, occupying most of the central and eastern regions; and the enviable title of Arabia Felix, or the Happy, is, comparatively speaking, merited by the beautiful and on the whole fertile lands in the south-west quarter, on the shores of the Red sea and Indian ocean. But other distinctions, established in the course of political revolutions, and become familiar to Europeans in the progress of geographical discovery, require to be specified. Of these the following are the most noted: Yemen, an interesting and much celebrated province in the south-west angle, described by Sir William Jones, in his Essay on Asiatic Poetry, as a kind of paradise, not more gratifying to the senses than calculated to excite the energies of creative imagination; Hedjas or Hejas, a district stretching on the coast of the Red sea, to the north of Yemen, and presenting some of the objects and places most memorable in the page of Arabian history; Hadramaut, a large province lying on the south coast, eastward of Yemen; Schadschar, or Seger, and Mahrah, two tracts partly sea-coast and partly inland, still farther to the east; Oman, a detached and hilly province, which forms the eastern corner of Arabia, at the mouth of the Persian gulf; Lachsa or Bahrein, as it is sometimes called, situate on the western border of that gulf, and of course opposite to the kingdom of Persia; and Neged or Nedsjed, a very large inland country, comprising the two districts of Ared and Kerge, and extending across the peninsula so as to occupy most of the central regions. All of these provinces, or states, as they may be called, from the circumstance of separate and tolerably independent governments, are subdivided into smaller districts.

Appearance.—Arabia has been variously described —as bearing a strong resemblance to Africa in its larger features—as a group of mountains encircled by an immense belt of sandy deserts—or as a vast, flat, and unprofitable plain, skirted by fertile elevations, and sparingly studded with verdant patches. The accounts on the whole concur as to its general unproductiveness and gloom, and its partial exuberance and splendour, but differ somewhat in the allotment of those extraordinary discordancies. We may safely hazard the assertion, that with some few exceptions, chiefly on the shores of the seas by which it is enclosed, Arabia is a dreary arid waste, scarcely fitted for animal habitation, and almost utterly precluding the visits of travellers, by the fervour of the tropical rays to which it is exposed, and the want of those common blessings which are essential to the support of life. Some stinted herbage, and other feeble indications of moisture, occasionally, and at terrific distances, tantalize rather than gratify desire; but wood, water, and fruit, are hardly to be met with in many days journey; the air itself, which in other countries affords so salubrious a refreshment, is often, by its heat and noxiousness, the swift messenger of death; and even the earth, or rather the sand which supplies its place in this region of calamities, not unfrequently joins in the alliance against the presumptuous passenger, rising up into waves more dangerous and scarcely less lofty than those of the ocean, and threatening every moment to obliterate every token of his existence. By some of these means, particularly the last mentioned, whole caravans and armies have perished, without leaving a single memorial of the catastrophe.

Climate, &c.—The characteristics of the climate, it will easily be understood, are heat and drought. But there are some exceptions, especially in the hilly part of Yemen and on the borders of the Indian ocean. In the former, a regular rainy season prevails from the middle of July to the end of September; though even in that country, it is said, the sky is seldom obscured for an entire day, and in some of the plains a whole year passes without a shower of rain. The rainy season occurs earlier in Oman. A few hills scattered throughout the internal districts occasionally attract vapour from the atmosphere, which descends in small showers scarcely sufficient to prolong feeble vegetation among the thirsty sands, or is collected into small pools, the possession of which is eagerly and sometimes fatally contended for by the no less needy inhabitants and travellers. In Yemen, where the finest climate is enjoyed, and where the highlands are most distinguished by their fertility and agreeableness, the thermometer frequently and for long periods rises above 90°; but the average temperature of Arabia does not exceed 80° throughout the year.

Soil, &c.—The soil is generally thin and poor. But some crops thrive in different places with remarkable luxuriance. Grain of various kinds, as maize, millet, and wheat, are cultivated, but yield only sparing returns, in consequence, probably, of the very unskilful management adopted. Beans and barley are more plentiful. Rice and oats are almost quite unknown. Culinary vegetables, a variety of fruits, coffee, and sugar, abound in some favoured districts; certain provinces in the south have been long celebrated for aromatics and spiceries; and even the dismal monotony of the desart is now and then interrupted by the friendly palm-tree and the generous vine. Arabia is destitute of forests; but clusters, or groves of trees, are to be seen on some of its mountains, especially towards the west and south-west coasts. The botany is scanty and rather uninteresting. Among the larger productions in this department of natural history, may be enumerated several species of palm-tree, the orange, fig, apricot, and almond, all of which are considered indigenous; the tamarind, pomegranate, and cotton tree, supposed to have been introduced from Persia or India; to which may be added a great variety of melons and gourds, *mimosa nilotica*, which yields the gum Arabic of the shops, and the *amyris opobalsamum*, from which is obtained the costly gum of Mecca; and among the shrubs and herbaceous plants we distinguish the *ricinus* or *palma-christi*, the seeds of which afford by expression the valuable substance generally denominated castor oil, the senna, and liquorice, all three used in medicine.

Zoology.—The first place in the zoology of Arabia is due to the horse, of which it is considered by some naturalists the original country, though others refer it to Independent Tartary. The breed is small in size, but full of spirit, admirable for activity, and possessed of the noblest generosity of temper. Perhaps, indeed, the genuine Arabian steed is the most compact piece of powerful and efficient mechanism in the brute creation. The natives, who are justly sensible of their value, pay the utmost attention to their genealogy and education, carefully witnessing and registering the former, which is said, in some cases, to be several centuries old, and spending a great portion of their time on the latter. Next to the horse, in point of rank, and superior in certain important qualities, is the camel. This extraordinary animal appears to be a native both of Arabia and Africa; to the peculiarities of both of which countries it is very obviously accommodated. Its eastern title, *the Ship of the desert*, is well merited by a variety of excellencies, which fit it, almost exclusively of all the rest of the carrying race, for passing a desolate and unstable ocean of sand. The species found in Arabia, according to Niebuhr, is that with only one hunch on its back, commonly denominated the dromedary. This is said to be much lighter, and to have far more speed than the other sort with two hunches, which seems to prevail most in the Crimea and Tartary. In the list of quadrupeds are mentioned the hyena, jackal or chacal, panther, wild boar, wolf, fox, monkey, and jerboa. Eagles, vultures, the ostrich, and pheasant, are met with. Land-tortoises and locusts are sometimes used as food. The variety of the serpent kind is considerable; and some of them, particularly a very slender species, called *beatan*, give a bite that is said to prove speedily fatal.

Mineralogy has not hitherto received much acquisition from this country. The precious metals are no where found in it, with the exception of a small portion of silver in the lead mines of Oman; and of the richer gems, it is not certain that any are to be met with which have not been brought from India in the course of commerce. The onyx-stone has been discovered in Yemen; a kind of agate, called Mocha stone, comes from the place so named, near the strait of Babelmandel; alabaster, selenite, basalt, and various sorts of spars, are enumerated by Niebuhr among its more common productions. The mountains in general, it is believed, are of the *primitive* order; and the ever-memorable Mount Sinai, in particular, is said to exhibit two striking summits of red-coloured granite.

Population.—The Arabs are an original and a very ancient people. They boast of a descent from Ishmael, the son of Abraham, by his concubine Ha-

Arabia.

gar; and perhaps have undergone fewer changes of feature or character than any of the eastern nations, all of whom are so much noted for permanency of manners and customs. Some circumstances render it probable, that the southern provinces were peopled even earlier than Abraham's time, by a branch from the same stock, whence the Assyrians had their origin. But the distinction, though sometimes kept up by prejudice and animosity amongst the natives themselves, vanishes from the view of the philosopher, who sees only one characteristic generation, merely modified, like the casts of India, by peculiarities in their occupations and modes of life. Of this kind it is necessary to mention the threefold classification, into Bedouines or Bedoweens, Mædi or Moædan, and Fellahs. The first, in whom the national peculiarities are most strongly marked, maintain an irregular and desultory residence in the desert, living under tents, and rarely visiting any of the towns, which are mostly situate on the coast. They are remarkable for activity and the love of independence. The Mædi are shepherds, whose employment requires and produces greater steadiness of character and longer continuance in one place. The last class includes the agriculturists, who are, of course, still more restricted to a fixed abode, and are confined indeed to few and very distant portions of the country. The inhabitants of the cities are understood to have suffered material changes in the progress of time through the influence of political events, and differ considerably therefore from those of the country. It does not appear that the population is any way proportioned to the vast magnitude of this region, which is readily explained by what has already been mentioned; but of its amount no satisfactory estimate, and scarcely, indeed, a plausible conjecture, has been offered.

Government.—Arabia is divided among a number of chiefs, having different titles and powers, almost entirely independent of each other, but occasionally acknowledging one nominal head, and sometimes really united for one common purpose. The principle of government which prevails is that of a father over his family. His power is almost unlimited, and it is generally hereditary. But the chiefs of the tribes, who are usually denominated Sheiks, or Schiecks, have been sometimes deposed for their tyranical conduct; and those sheiks who have associated under a common chief, exercise the right of appointing his successor, who is generally chosen, indeed, out of the same family, but not without due regard being paid to superiority of talents for the office. This privilege, and the power of deposition, render condescension and mildness of behaviour very requisite on the part of the grand sheik. The sheiks possess no fiefs, as in the feudal governments, but have a kind of property in the persons of their subjects. They lead the armies, administer justice, either directly or by deputy, and decree peace and war, but seldom without taking the advice of competent persons in the tribe. The structure of the genuine Arab government is altogether remarkable for simplicity and force. But in modern times, and chiefly through the agency of a religion highly favourable to despotism, if not refinement of policy, various distinctions and institutions, formerly unknown, have taken place, and they prevail most in those parts of the country where civilization has made the greatest progress. Under such an influence, unequivocal resemblances to the monarchial establishments of other Asiatic countries appear. The title of *imam*, which implies vicar, that is of Mahomet, is, properly speaking, ecclesiastic, but is often applied to chiefs of superior dignity, and becomes synonymous in some instances with the better known name of *caliph*. It is therefore given to the sovereigns of several provinces, and appears to entail a greater degree of authority and consequence than is possessed by the sheiks. An imam, in fact, is the head of a country, rather acquired by conquest, than voluntarily associated under him, having various tributaries, who are sometimes the sheiks themselves, and possessing the almost entire and unrestricted administration of civil, ecclesiastical, and military affairs, which, however, he finds it convenient to allot to subordinate and responsible officers. But though absolute, generally speaking, it seems, according to Niebuhr's information, with respect to Yemen at least, that his authority over life, if not some other important concerns, is liable to check from a tribunal of which he is merely the president, and before which all capital cases must be decided. This restraint is probably more nominal than real, and is rarely exercised: Such is the inference to be drawn from the circumstances of the imam appointing the assessors of this tribunal, and his having the power of removing them at pleasure. We are told, indeed, that these sovereigns have never found their advantage in violent measures, and that acts of tyranny have commonly ended in the destruction of the agents. This may be true; but the very fact itself proves the influence now suggested, though the testimony of experience condemn its exercise.

Ranks, &c.—There are many public officers, but few titles of honour in the court of the imam. His first minister is styled *fakih*. This term is somewhat equivalent to our *gentleman*, and can scarcely be thought, therefore, to denote uncommon dignity. The titles of *wali*, *dola*, and *emir* are given to the subordinate governors of districts, but this last name is not unusually considered of equal import with *imam*. *Sherriffe* is the denomination of certain descendants of Mahomet, who posses sovereign power in some cities of Hedjas. *Mufti* and *cadi* signify persons engaged in the ecclesiastic and civil judicatures. But the prince himself is usually the high priest, as well as the supreme judge.

Religion.—Arabia is the birth-place of Mahomet, and the country in which he first established his doctrines. The Koran is universally received as the standard of faith; but according to the prediction of that singular man, and as might, indeed, have been expected, from the caprices as well as the improvement of human nature, it has given rise to a variety of sects, who are exceedingly hostile to each other. In general, it has been said, they are more remarkable for credulity than purity of morals. Of late years, a sect differing essentially from all other believers, and called after Waheb their founder, has made astonishing progress in overturning both the religious opinions and the political establishments of this country.

Commerce, &c.—Previously to the discovery of the course to India by the Cape of Good Hope, the commerce of Arabia was very extensive. Since that period it has rapidly declined. The exports, which are chiefly from Yemen, consist of aloes, myrrh, senna, and a few other drugs, frankincense, and coffee. The Arabs import the useful metals, either in mass, or wrought into various implements and utensils, glass, colouring substances, certain kinds of cotton goods, and different luxuries. These imports are rarely from Europe direct, but are supplied from the European settlements on the coast of India. Africa furnishes Arabia with ivory, gold, and slaves. The few manufactories carried on in this country are generally in the hands of strangers, who reside in the cities and towns on the coast, especially that of the Red sea. But the natives appear to be endowed with every intellectual faculty requisite for their perfection, and to need only to be encouraged to excel.

Cities, &c.—Arabia cannot boast much of its cities. Mecca is the most famous; but being sacred among the believers of Mahomet, and in consequence inaccessible to the people of any other religion, it has seldom or ever been described in a satisfactory manner. It is situate a full day's journey from Jidda, or Jeddo, a port nearly about the centre of the eastern shore of the Red sea. The buildings, which are mostly of stone, are said to be better than those in any other city in Arabia. Excessive heat prevails in it during the summer months. The inhabitants are wont to shut their windows to avoid it. They water their streets also, in order to moderate the temperature. But it is not unusual for persons to be suffocated by the burning wind called *Samoum*, or *Samiel*, if accidentally exposed to it. Of the size and populousness of this city, no correct information has been obtained. The principal edifice, from which it derives its importance in the minds of the orientals, is the Kaba, or Caaba, i. e. House of God, in which is deposited the most precious object of Mahommeddan superstition. This is a black stone, said to have been brought by the angel Gabriel from heaven. It was at first, according to report, of a bright white colour, so as to dazzle the eyes of the beholder; but being of a compassionate nature, and having wept long for the sins of mankind, it gradually lost its complexion and clearness, and at last assumed its present hue and opacity! In point of architecture, the Caaba is an awkward, clumsy building, totally unworthy of notice. There is decisive reason to believe, that, even earlier than the days of Mahomet, this city was highly venerated by his countrymen, and that he merely availed himself of the current opinion to enhance its importance. The governor of Mecca, previous to the time of Waheb, was a temporal prince, whose revenue was augmented by gifts from the various sovereigns professing the same faith. Medina, to the north of Mecca, at the distance of about 200 miles, and like it about a day's journey from the coast of the Red sea, is but a small place, without any thing remarkable, except the tomb of Mahomet, which is erected in a mosque, and is of plain mason-work, in the form of a chest, inclosed within iron rails, for the obvious purpose of keeping the populace at a distance, who are said to have been in the habit of throwing dirt upon the tomb, which they afterwards scraped off, and preserved as a relic. In this circumstance, we apprehend, may be seen the origin of the absurd report so prevalent amongst the Mahometans, that the coffin of their prophet is suspended in the air by means of magnets. Pilgrims usually visit the tomb, but this is not essential to any religious exercise. It is placed between two tombs, in which are deposited the remains of the two first caliphs, and is not more magnificent than those of the founders of most other mosques. The building which covers it is decorated with a piece of embroidered silk, and was commonly guarded by forty eunuchs, for the security of the precious stones and other treasure occasionally offered to it by wealthy Mussulmans.

Sana or Saana, at the bottom of a mountain called Nikkum, in the south-west part of Yemen, is a large town, reputed indeed the chief in Arabia. It is about four miles in circuit, but much of the space is occupied by gardens. The houses are mostly built of bricks dried in the sun, fuel being very scarce. The walls are of the same material, and have seven gates, and there are several palaces, some of which are of stone. It is a place of some trade. Some small streams fertilize the neighbouring country, which is noted for its beauty and rich fruits. The palace of the governor, or prince, which is at a little distance from the town, is denominated "the castle of delights," a phrase very agreeable to an eastern imagination.

The town of Mokka, Mocho, or Mocha, which lies near the entrance of the Red sea, is an indifferently built place, containing about 10,000 inhabitants, who are chiefly occupied in trade, and possessing a convenient harbour for small vessels. The coffee which comes from this town, and which constitutes its prime commodity, is in the highest esteem throughout the world. Our countrymen have of late years almost entirely engrossed the trade of this thriving place.

Jidda, or Jeddo, the sea-port of Mecca, is small, situate in an unhealthy barren tract, badly supplied with water.

The province of Hadramaut, according to the scanty intelligence which Niebuhr collected, appears to contain an immense number of towns and villages. Of those he has mentioned, the following may be considered most important. Schibam, about eight days journey from Sana, the seat of a powerful prince, and perhaps the Saba of the ancients; Keshim, a sea-port, visited by the English; Dafar, or Dofar, a sea-port, near Cape Morbat, noted for its exports of incense; and Ainad, greatly to the east, famous for a fair, and for the tomb of an ancient prophet, called Kachtan, or Jaktan, spoken of in the Koran.

The towns of Oman are not worthy of description. It is enough to specify the names of Sur, Kalabat, Kuriat, and Muscat. This last place was formerly of consequence in the hands of the Portuguese, but since their expulsion by the Arabs it has gradually declined. In respect of position, at the mouth of the Persian gulf, it lies well for trade, and seems to court the visitation of strangers. English vessels coming from India not unfrequently touch at it.

Lahsa, the capital of the province so called, on the Persian gulf, is a goodly town by all accounts, but is comparatively little known. There is a pearl-fishery in its vicinity. Some maps lay down a river as entering the gulf at this place. In all probability it is merely a brook, only sometimes filled with rain from the mountains in Neged. Katif, to the north of Lahsa, was once important. The Portuguese had a fortress near it, the ruins of which were to be seen in Niebuhr's time. Koueit, Græn, or Grane, is farther to the north. Its inhabitants carry on a pearl-fishery. Here also the same people had a fortification.

Several islands in the Persian gulf are subject to the Arabs. The towns, or rather villages, of the desert, have little claim to attention.

National character.—It is not easy to give a faithful representation of national character, even where the materials are constantly in the view of the observer, and have become familiar by frequent examination. The manners and the conduct of a few individuals are too apt to obtain undue consequence in his mind; nor is it always practicable, however voluntary and conscientious his efforts may be, to divest himself of prepossessions, arising as well from the peculiarities of his own temper and disposition, as from the education and treatment to which he has been subjected. In general, it may be observed, that professed estimates of character, in the abstract, are either faulty from the causes now mentioned, or partake much more of the fancy and the method of the composer, than the substance and irregularity of fact. A safer, though less splendid delineation, is afforded in the detail of specific manners and customs, which, though by no means exactly either the cause or the consequence of national character, have sufficient power to modify it, and give prominency to its essential features. It is certainly allowable to deduce inferences from these indications, to a certain extent; but in every such process we ought to recollect, that human nature is the same throughout every region in which it is to be found, and that our conclusions must never imply any radical differences of its constituent parts. In other words, we must confine ourselves to the mere varieties of modification under which that nature is presented. These reflexions, obvious and elementary as they are, will be found important in all cases where the diversities of nations are considered, but are more imperatively necessary when every step of our inquiry leads us to some institution or practice quite at variance with our own habits, and indeed, at first sight, utterly irreconcileable with those notions of propriety or expediency with which we have been imbued. The instance before us demands this caution in the highest degree. No two creatures, in fact, appear more unlike than the genuine Arab and a native of any country of Europe; and yet a close investigation of the most glaring dissimilarities will terminate in the conviction, that both have the same origin, and partake of the same nature. But it is time to attend to some of the discriminating features of the former.

Boys, in Arabia, are commonly confined among the women till the age of five or six, when they are removed to the company of their fathers, from whom they acquire a gravity of manner which despises the trifling employments of youth, and a habit of thoughtfulness which scarcely admits the necessity or recognises the influence of ordinary pleasures. They early become men, capable of encountering the difficulties of their lot, and worthy of confidence in those offices and duties to which they are called by their own ambition or the prejudices of the tribe. Their seriousness is quite consistent with vivacity of disposition, though this displays itself rather in promptness of action, where some valuable object is to be obtained, than in the greedy prosecution of licentiousness, or the inordinate demand for trifling amusements. They are fond indeed of company, but apparently for reasons derived from the same source, because it affords room for ingenuity, emulation, and the intercourse of thought, not as administering occasion to intemperance, or encouraging vice by the force of example. A good, but perhaps a partial judge, Sir William Jones, does not scruple to denominate them a "majestic race," and describes them as having "eyes full of vivacity, their speech voluble and articulate, their deportment manly and dignified, their apprehension quick, their minds always present and attentive, with a spirit of independence appearing in the countenances even of the lowest among them." Some explanation, perhaps, may be given of their claims to so high an eulogium. Hitherto, with the exception of those towns and their immediately adjoining districts in which usurpation and tyranny have engendered indolence and debauchery, the Arabs have had to contend almost perpetually for their liberty by personal valour, and therefore no individual has been suffered to think himself exempted from the restraints of military virtue. But it must be admitted, on the other hand, that their excellencies are not without alloy. Nay, they almost necessarily produce some unhappy evils. Thus, the Arabs are vindictive beyond the ordinary measure of wrath, carrying animosity for the greater part of life, and inflicting punishment on the most innocent relatives of the hated object; their pride is so irritable, that it is raised to madness by the slightest disrespect, and so lordly, that it requires the blood of the offender before it can be appeased; their activity is the fruitful source of unjust and cruel aggression; and in the maintenance of their own freedom, wild and lawless as it may be, they would not hesitate to inflict the most degrading slavery on all the rest of mankind. In addition to these most serious charges, which, unfortunately, many particulars in their history serve to substantiate, they have been represented as despicable cheats and arrant hypocrites. But Niebuhr testifies the exaggeration, if not the falsity, of this odious estimate; and it is very certain, from his account, that they are ready to admire the beauty, as well as to admit the value of good faith and honest behaviour. As a warrior, the Arab is entitled to unqualified praise. No danger appals him which it would not be madness to encounter; he appears always confident of victory, but never neglects the means by which it is to be accomplished; and in the midst of the greatest difficulties and suffering, he consoles himself with the certainty of future happiness, should his bravery fail of a present reward. His onset is terrific, overwhelming, decisive; nor is it the least of his martial qualifications, that he has the skill to make his faithful companion contribute to his success by its strength, or ensure his safety by its speed.

State of Women, &c.—The condition of females in this country, is, on the whole, comfortable, though they be denied access to assemblies, as fit only for men, are interdicted music and dancing, as indecent, and are occasionally subjected to the divided regards of their husbands. Polygamy, though allowed, is far from being general, most of the Arabs finding a single wife abundantly expensive for their finances. It is the rich, therefore, who indulge in a plurality, unless in cases immediately to be mentioned, where marriage is a sort of commercial speculation. Divorce rarely occurs, and, indeed, is rather dishonourable, except when the most warrantable of reasons enjoin it. A woman may exercise it, if she find herself ill used. In this case, she is entitled to her dowry, over which, according to the equitable custom of the country, she continues to enjoy the power, even in the married state. It frequently happens, therefore, that a man is dependent on his wife, whom it is consequently his interest to please, and from whom he cannot separate without loss. For these reasons, rich parents will bestow their daughters on poor men, rather than on the wealthy. But it is no less true, on the other hand, that fathers in the lower ranks sometimes add to a list of wives in expectation of presents from their sons-in-law. Marriage, altogether, is eagerly sought by the women, who universally consider it disgraceful to be without children. They will in consequence content themselves with the poorest husband, and even submit to have partners in his affection, rather than incur the reproach of barrenness; and as the men, again, profit by their dowry or their labour, there are few persons who continue single beyond a certain early period of life. Wives possess great authority in their families, and are treated with courtesy and tenderness, which they seem to deserve by their becoming conduct and affectionate solicitude. The women in general are cautious against being seen, and it is thought very unpolite to look them stedfastly in the face, if on any occasion uncovered; yet they will sometimes kiss the hands of a man of distinction, and even kneel to kiss his feet.

Hospitality, &c.—The Arabs are very attentive to strangers, liberal in the distribution of their substance to those who need, and far from being so narrow-minded as to exclude from their friendship persons of very different religious opinions. All creeds indeed are not equally respected, though all be tolerated, in the widest sense of the word. Christians meet with least aversion—then Jews—the Banians of India are most disesteemed;—but any one of these may experience the hospitality and kindness of an Arab whose honour has been engaged by confidence, or with whom he has once had the good fortune to partake of a common meal. It is good policy in a traveller, therefore, as soon as possible to secure Arabian protection by a social repast, the instances of treachery, after such an implied engagement, being too rare to justify the least suspicion. An Arab, in reality, appears to proclaim his hostile intentions by refusing to be entertained.

Salutations are numerous and respectful. 'Salam Aleikum,' 'Peace be with you,' is a common form. They shake hands—a superior suffers his fingers to be kissed—equals embrace—pipes and perfumes are presented at ordinary visits, and guests are sprinkled with rose-water when about to retire. The greatest care is taken to promote and preserve cleanliness of person. Temperance in eating and drinking is almost universally practised; and certain indications of over-repletion or indigestion are reckoned so disgraceful, that a man has been known to fly his country after a transgression which no legislator has ever yet deemed immoral. The superstition of the Arabs induces them to wear amulets and use charms. Their religious worship is performed with commendable humiliation, and is always preceded by stripping off their rings, jewels, and other ornaments. Both sexes are subjected to circumcision in early life.

Language, &c.—The Arabic language, it is well known, is exceedingly ancient. It is no less remarkable for its copiousness and nice adaptation to the varieties and complexity of human thought. The cultivation of it appears to have constituted a national and universal object of regard in the earliest times, and hence an abundance of compositions both written and oral, with which few other countries, if any, can compare. Those dialects which are now in common use, vary very considerably from the language of the Koran, which appears to have been adopted by Mahomet from the tribe of the Koreish, to whom had been committed the preservation of the temple of Mecca, so long the central point of the national faith. Mahomet himself thought so highly of that language, that he sometimes appealed to his book as indisputable proof of his divine mission. Niebuhr thinks the differences of the prevalent dialects equal to those found in the states of Italy, and in a few cases to be about as great as are exhibited by the Spanish and Portuguese.

Reading and writing are common qualifications among those who engage in business; but, on the whole, education is very limited both in kind and quantity. The acquisition of learning does not appear to exalt the consequence of an individual, as, according to Niebuhr, he is rarely, on that account alone, promoted to any higher office than that of a schoolmaster or transcriber. The less fortunate literati are often forced to gain a livelihood by reading or reciting for the entertainment of those who frequent the coffee-houses, a place and species of recreation very common in Arabia. Whatever they were in former times, it is pretty certain that neither poetry nor eloquence is now in a prosperous condition; but the very circumstance just now mentioned implies a degree of taste beyond the sensuality of vulgar minds. Science, formerly also highly cultivated, is equally defective among the Arabs. Their astronomy is little better than a system of astrological quackery, of which they are still the dupes. Other occult studies are in repute; whence we may infer the absence of true philosophy. Medicine is wretchedly practised, and no less wretchedly recompensed. "All the physicians in Yemen," says Niebuhr, "with whom I was acquainted, acted at the same time as chemists, apothecaries, surgeons, and horse-doctors, and yet, by the practice of all these arts together, they could scarcely make a livelihood."

Mode of eating, &c.—The Arabians, like most of the eastern nations, squat themselves on the ground at meals, of which they partake with the hand, not making use of knives or forks. They generally place a long linen cloth under their knees, instead of a table-napkin. However numerous the party may be, it is usual for the whole to put their hands into the same dish in which the victuals are presented. But as they pay the greatest regard to cleanliness, Niebhur says that in reality their mode of eating is little less delicate than that of Europeans. It is managed with surprising rapidity. Among their common dishes are, boiled rice, milk, butter, whipped cream, and pastry of various sorts; animal food is little used; bread made of coarse millet-seed, kneaded with camel's milk and oil or butter, is eaten by the poorer people. Though mills for grinding are known, the Arabs generally prefer the practice of bruising their corn, as yielding a sweeter flavour. The usual beverage is water, either pure or with some simple addition; but strong drink, though forbidden by the Koran, is occasionally indulged in privately, when it can be procured.

Dress, &c.—The ordinary dress of the Arabs is very simple; a large shirt, either white or striped with blue, a loose cloak, or mantle, a pair of drawers, and a kind of turban, which consists of a number of linen or cotton caps. This head-piece is represented as both cumbersome and expensive, the people of rank wearing sometimes no less than fifteen folds, the uppermost being embroidered with gold. It forms an excellent defence against the heat of the sun, which might prove fatal if not thus excluded. The men of learning are often distinguished by the magnitude of their turbans. Sandals are used in place of shoes, but people of fashion wear slippers. The women veil their faces; rings are applied to the nose and ears, as well as to the fingers and arms. It is usual to stain the nails red, to paint the circles of the eyes and even the eye-lashes black, with a metallic preparation called *kochlel*, and the hands and feet are often died of a brownish-yellow colour. The natural complexion is a deep yellow, though persons with fair skins are sometimes seen. The men shave their heads and preserve their beards, but there are various exceptions to both practices. When the latter become white from age, some fanciful folk contrive to give them a reddish hue; the folly of the device, however, is so obvious, that, on the whole, there are not many who adopt it. Fashion exerts her sway here as elsewhere, but, in general, is not very capricious.

The Arabs are of the common stature, and are slenderly made, or, more properly speaking, seldom become corpulent, in consequence, no doubt, of their moderation, or rather abstemiousness as to eating and drinking, and the freedom and frequency of exercise to which they are accustomed.

In concluding the account of this interesting people, it may be proper to mention, that the best traits of the character assigned to them are most certainly found in those parts of the country where the state of society is somewhat between the extremes of ungoverned licentiousness and the oppression of unmitigated despotism. Nothing can be more unjust than to draw their picture from those ruffian bands in the northern boundaries, who have for ages carried on a system of pillage and cruelty, which has invested the name of Arab with the most terrific and detestable associations. The descriptions given of *them* by travellers in Egypt, Syria, &c. are nearly the most hideous pictures of human depravity. One of the last of these we have seen is in Jackson's Account of Morocco, in which are detailed the particulars of the treatment experienced by Europeans, not excluding our own countrymen, be it remembered, who had the misfortune to be taken, by whatever means, either *on* or *off* the Barbary coast, and who, after being plundered, were sold as slaves to these vile miscreants. Britain, it must be allowed, had too long and too supinely overlooked such enormities. Humanity, now somewhat hopeful, waits to learn whether the voice of indignation, at length extorted, shall prove effectual for their prevention.

History.—The early history of Arabia is extremely obscure. It may be traced, with some semblance of probability, to Assyria, one of the first civilized countries of which we have any satisfactory accounts. A tradition among the Arabs themselves derives some of their sovereigns from the neighbourhood of Samarcand. These appear to have been worshippers of fire, and were styled *Tobba*, which was either their family or their official name, like the Pharaoh of the Egyptians. A correspondent opinion, prevalent in Persia, affirms, that the conqueror who founded the ancient capital of that kingdom came also from the same country, and hence is presumed the connexion between the Persians and Arabians. Niebuhr endeavours to confirm this inference by the circumstance of the similarity of character noticed by him in certain inscriptions met with at Mocha and Persepolis; from which, of course, he deduces likewise the identity of language used by these people in ancient times. But there is some imperfection in the evidence, which, though not sufficient to discredit the theory, must necessarily abate the confidence of a cautious inquirer.

It is more certain that, previously to the era of Grecian history, the Arabs had attained considerable power as a nation, in which capacity they acted an important part in the theatre of the world. Thus the shepherd kings, as they are called, who invaded and conquered Egypt, are, with great probability, imagined, by Bryant and others, to have proceeded from part of this region, or at least from the land of Babylonia, which is judged to be the original seat of the Arabs. It was in memory, it is believed, of two of the cities in their own country, that these people, denominated *Auritæ*, from *Aur*, a Hebrew word signifying fire, which was the great object of their worship, built a place of the same name, but corrupted into *Ur*, and Babylon in Egypt. But Memphis was their chief city in that land, into which they appear to have established their own religion. They were

Arabia.

expelled from Egypt after a residence, and indeed a tyranny, of more than 400 years duration.

Of the state and fortunes of Arabia itself in this period, we have only the most vague and imperfect conjectures. During the successive empires of the Persians, Greeks, and Romans, the affairs of this country were almost altogether unnoticed by historians. All of these powers appear to have made attempts, some of them frequently, to subdue it, but with very insignificant success. Thus the Arabs, then, may boast of an exemption from foreign dominion probably unexampled in the records of any other people of equal importance in civilisation. Their independent constitution of government was not less singularly prolonged. It does not appear that Arabia was ever united under one head till the period of Mahomet and his immediate successors; and even then the union was merely nominal with respect to several tribes. Kings of the *Hamjare* or *Hamiar* race, it is true, reigned over considerable parts of it, more especially Hadramaut; and the provinces of Yemen, besides having been repeatedly and successfully invaded, as Gibbon notices, were also occasionally governed by one sovereign. But the rest of the country, and particularly the internal districts, must be allowed to have continued free from both species of subjugation. This remarkable peculiarity in Arabian history, has been treated of by the writer now named, with his wonted vigour and sagacity; but he has not suffered the exceptions just hinted at to escape him, without a sarcastic sneer at the indiscretion of certain authors, who had drawn conclusions from the Arabian independence in support of a system, which neither required their officiousness, nor can be injured by his malignity.

Religion of Mahomet.—Though both the Jewish and Christian religions had been introduced into Arabia before the time of Mahomet, the former, probably, by Jews from Ethiopia, whither they had fled from Roman enmity, and the latter at least as early as the middle of the third century, if not at the very commencement of its success among the heathens, it does not appear that his countrymen had advanced far in refinement of manners, or the cultivation of the arts and sciences. Some of the chief nobility, it is likely, and the men of learning, were so far enlightened as to have become pure theists. But their influence was very small over the prejudices and stupidity of the vulgar mass, which still remained sunk in contemptible idolatry. A system, which, without violently opposing popular indulgencies, inculcated opinions become fashionable among the great, had some reasonable chance of succeeding with a people of lively intellect and warm imagination. Mahomet, accordingly, seems at first to have relied entirely on the power of persuasion in promulgating his doctrines; and it is highly probable, that at this time he himself had the firmest belief in the truth of what he taught. But the conversion of about fourteen persons in the space of three years, did not correspond with the enthusiasm of his feelings. He now gave himself out as a prophet, and perhaps thought that he was one. In the course of ten years following this assumption, he laboured publicly, and with considerable effect, especially among his fellow-citizens of Mecca. His success at length alarmed the friends or interested adherents of the ancient idolatry, particularly the Koreish, from whose determined opposition and threatenings he was induced to consult his safety by retiring to Medina. This flight, which took place in the year 622 of the Christian era, from its mighty consequences, became the epoch of his disciples, under the name of *Hegira*.

Arabia.

Propagated by arms.—At Medina, where his pretensions had already been known and admitted by many, Mahomet endeavoured for some time to conciliate his opponents by gentle means; but as these did not answer his expectation, and as there appeared a necessity for vigorous measures to ensure his welfare and the extension of his cause, he had recourse to arms, and asserted the duty of combating for the faith. The sword was found quite agreeable to his doctrines, and a much fitter instrument for making converts than any he had hitherto employed. Victory followed victory, and in a few years the banners of the crescent waved over all Arabia. Mahomet died in 632, at Medina, where he commenced his military career, and which henceforward was sacred to his memory, though, for reasons already assigned, and after having failed to procure the countenance of the Jews, by appointing Jerusalem as the place to which prayer should be addressed, Mecca was still regarded as the holy city. His countrymen, now united in his faith, and acknowledging him for their spiritual head, were not by any means altogether subjected to his temporal power. Some tribes, on the contrary, no way diverted from the love of freedom by fanaticism, maintained their independence under their own chiefs, both during his lifetime and in the reign of his successors. This anomaly was most conspicuous in certain provinces bordering the Red sea, and seems strangely inconsistent with the rapid and wide spread influence of so militant and domineering a religion.

Causes of its success.—The causes of the extraordinary success which attended the doctrines of Mahomet, have not been well understood. "That a victorious imposture should continually extend its influence," says a late very judicious writer, "amidst the deplorable dissensions which then dishonoured the Christianity of the east, may be easily comprehended; but the question is, how it acquired sufficient strength to become a victorious imposture." The ignorance of the Arabians, and the disunion of their numerous tribes, to whatever degree they may be supposed to have amounted, explain rather negatively the comparatively little resistance which he experienced at his outset, than positively the facile adoption of his opinions, which perhaps, had they been of another description, would have met with universal apathy and contempt. That catholic adaptation of his creed to the peculiarities of every existing system, which is one of the most striking features in his missionary conduct, is scarcely adequate to the difficulty; because, as is noticed by the same writer, his success was obtained at Mecca, whereas the Christians and Jews, whom he was so anxious to placate by his condescension, resided chiefly at Medina. The solution, therefore, is sought for "in the intrinsic merit of the doctrines which he preached." "To ignorant heathens," continues Dr Millar, "he taught doctrines which were borrowed from the pure system of divine revelation, much debased indeed, but still far nobler, and more worthy of attention than the rude tenets of their native paganism; and ignorant as they were, and incapable of forming a just judgment of his pretensions to divine authority, these heathens were yet in that state of pastoral refinement in which they could be captivated by the charms of eloquence, and be struck with the sublimity of the scriptural descriptions of God. The religion of Mahomet is, in reality, a coarse modification of divine truths, brought down to the capacity of barbarous nations; and was probably better adapted to their moral regulation, than the contentious and paganized Christianity, which alone preserved among them the memory of the gospel." [*Philosophy of Modern History, Dublin* 1816.]

This specious elucidation, so complimentary to human nature and the sagacity of Mahomet, seems to require material qualification before it can be adopted as even partially correct. Its justness is rendered questionable by a fact noticed by the author himself, viz. the small success which Origen enjoyed in his labours to proclaim the doctrines of a work from which it is admitted that Mahomet derived his most important sentiments. In our opinion, the chief influence is to be ascribed to the novel circumstance of a native Arab displaying the ceaseless energy and the solicitude of an apostle, which could not fail to produce a very general conviction of the really interesting nature of his communications.

Successors of Mahomet.—Mahomet had named Ali, his son-in-law, for his successor. But Abubeker, whose daughter he had married, frustrated his intention, by gaining over the army to his own interest. This able man prosecuted the military plans of the prophet, and extended the new faith beyond the boundaries of Arabia. Jerusalem and Damascus, at this time part of the eastern empire, yielded to his arms. The reduction of Persia was effected in the reign of his successor, Omar, who was elected to the caliphate by the splendid and significant title of Emperor of the Believers. This important conquest proved advantageous to the Arabians in another manner than by merely extending their dominion. It rendered them in fact the willing disciples of a people much more advanced in refinement than themselves, Persia proving to them what Greece had been, in an earlier age, to its masters the Romans.

Omar was murdered by a Persian during his devotions at Medina. The caliphate was then filled by Othman, on whose death, Ali, who, from prejudice, or other not well understood reasons, had been deferred, succeeded to sovereign power. His reign was splendid, though of short duration, and full of trouble. Hasan, his son and successor, was speedily deposed, and afterwards murdered. During these five caliphs, Medina continued to be the seat of government. The new race of the Ommiades chose Damascus for its residence, and has consequently been denominated the Syrian Dynasty. It lasted for about 90 years, when it was succeeded by the Abbassides, the descendants of Ali, who built Bagdad, on the Tigris, where they reigned for nearly five centuries, the last of the caliphs being put to death by the Tartars, at the capture of that place, in the middle of the 13th century. This long period, which coincides with the dark ages of European history, was illustrated by the brightest efforts of Arabian literature and science, though the caliphate had lost its military importance and extensive empire. The names of Haroun al Raschid, so signalized in that marvellous work the Arabian nights tales, and his son Almamon, the munificent patron of learning, adorn the list of the Abbassides.

The Mahomedan religion, with various modifications and sundry dissentions, now prevailed from Hindostan to the northern regions of Africa, and had actually extended through Spain to the Pyrenees, if not into France, as far as the Loire. But these diversified regions acknowledged a variety of sovereigns besides the caliphs of Bagdad, whose influence at last became a mere shadow of what it had once been.

Arabia, enjoying a state of independence under its indigenous chiefs, appears to have remained much unnoticed till the arrival of the Portuguese in the Red sea, subsequently to their discovery of the course to India by the Cape of Good Hope. This induced the sultan of the Mamalukes, El Gury, to fit out a naval force, for the purpose of opposing them, and which, availing itself of the opportunity, seized almost all the sea-ports in that sea belonging to the Arabs. These places fell again, for a short time, into the hands of the natives, when the Turks established their power in Egypt, but were afterwards taken possession of by that people, under Soliman Pacha, whose successors pushed their conquests over a great portion of Yemen, henceforward considered a province of the Ottoman empire. But the spirited chiefs of the interior defied the ambition of these new enemies, and by a bold resistance, followed up by repeated attacks, drove them to the coasts, which they were at last compelled to abandon, with the exception of a few places where they retained a mere semblance of authority. Even this may be said to have vanished, in consequence of some recent events.

New Religion.—It has been mentioned, that a new religious sect has lately arisen in Arabia, deriving its origin and name from Waheb. Its progress, the rapidity of which has been so alarming to previous establishments, is the only remaining portion of the history of this country deserving minute attention.

But we have to regret that the accounts of it hitherto published are both imperfect and contradictory. Abdul Waheb was a native of El Aiane in the province of Nedjed-el-Ared. After having finished his study of the sciences in Arabia, and travelled through Persia, he undertook to reform the religion of his country, condemning a variety of abuses, and endeavouring to introduce greater simplicity of faith and greater purity of conduct. Without derogating from the honour of the prophet as a divine teacher, he insisted on confining worship to the Supreme Being alone, of whom it seems pretty certain he entertained more correct notions than the Mahometans in general, though it be scarcely possible, from the information we have respecting his principles, to ascertain his peculiar sentiments. The doctrines of Waheb were eagerly adopted by some of the tribes, and shortly his influence began to be felt throughout

Arabia. a great part of Arabia. Opposition, of course, arose among the retainers of the ancient creed, who, as is usual, denominated reformation heretical, and thought it most convenient as well as most commendable to abide by an established faith. His enemies did not find him unprepared when they attacked him with an armed force in his native city. He obtained a victory over some thousands, which had the double effect of confirming his doctrine and augmenting his power. No wonder that it also excited his ambition and animated his efforts.

Success often inspires wisdom as well as energy. Waheb appears to have possessed both in a considerable degree. He now declared his opponents to be enemies of religion, and liable to punishment in their persons and estates; and as his ability to inflict it was already great and on the increase, several persons of the highest importance saw it expedient to submit to his authority, and to attempt the promotion, or at least the preservation of their own interests, by contributing to his measures. Thus his followers, originally consisting of the lower orders of the people, whom a specious delusion and the hopes of a favourable change had united under his banners, were rapidly increased, and obtained respectability of character from their consequence as well as their number. The whole of Neged declared in their favour, and Yemen now became the theatre of their successful exertions.

Progress of the Wahabees.—Mecca yielded to their arms in 1803, on which occasion they are reported to have committed the most enormous excesses and cruelties. From this city the chief of the reformers wrote a letter to the sultan, reminding him that the title of Caliph belonged to the protector of the holy city, and that therefore the dignity attached to it devolved on himself as the conqueror. The Ottoman armies, already in march against these enthusiasts, were unable to withstand their progress, almost all Arabia having espoused their cause, which was acknowledged also and maintained throughout many other parts of the sultan's real or nominal dominions.

The capture of Medina, now projected, seems to have been prevented by the breaking out of the plague and the small pox among the insurgents, who were even obliged to retreat into the desert, leaving only a few hundred men to garrison Mecca, which was soon retaken by the Turks. A truce followed, but was probably deceitfully entered into by both parties, as in a short time hostilities recommenced, and the interval seems to have been spent in animosities and mutual preparations for another contest. At what time the death of Waheb happened we have not been able to learn, the works from which we have hitherto derived our information differing in their statements. It seems to have been occasioned by the malice, or the zeal, of a fanatic, employed in the service of the Ottoman Porte.

Abduluziz succeeded his father in leading the new religionists to avenge the murder of their founder, and to establish his cause. In spirit, ambition, and intelligence, the son appeared to merit this distinction; nor did his fortune, at first at least, belie his exertions. Mecca was re-captured, and Medina taken, but he himself was assassinated at Darail by one of his countrymen, whose daughter he had long before carried off by force, and who had continued with most persevering diligence to seek a fit opportunity for revenge. The religion of Waheb was now most extensively spread, and seemed to defy farther opposition. Suud, the son of Abduluziz, was recognized as its head. It is by this person, we ought to observe, according to one account, that the capture of the two cities, Mecca and Medina, above mentioned, and the accomplishment of several objects were effected, which by others have been ascribed to his father and grand-father.

The conquest of Mecca, by whomsoever made, may in one sense be considered the death-blow to the superstition of Mahomet. This city, for more than a thousand years, had received the prayers and the gifts of the faithful; and during all that period was not once entered but with the intention of contributing to its glory and prolonging its claims to veneration. "It appears to me almost certain," says Mr Scott Waring, in the Account of his Tour to Shiraz, &c. that the pilgrimages to Mecca have had nearly as great an effect in supporting this religion, as the first victories and conquests of Mahomed." What substitute can be adopted for so essential a bulwark? Who, among the multiplied and greatly discordant followers of the prophet, is either entitled or able to supply its place, or to remedy its loss? Even the recovery of his temple, and the purgation of it by the blood of his enemies, which their present supremacy and augmenting force render a very improbable event, could not wipe away this calamitous stigma, nor vindicate the sacredness and the efficacy of the law which forbids the approach of armed men within a certain distance of its walls. Despair, then, and contempt may finish what selfishness and rebellion commenced; and, ere long, a system, to the dominion of which no limit could be discovered in the credulity or the patience of so great a proportion of mankind, may moulder down into the vanity of dead and forgotten things. "All they that take the sword shall perish with the sword," is a maxim more peculiarly applicable to every religion which promotes conversion by violence, and accepts of slaves for disciples. There must and will come a time when blood shall cry for blood, and will be heard by Him whose prerogative has been impiously assumed.

Reflections.—It is not our province to discuss the politics of the times, nor would our readers probably be inclined to relish conjectures and prophecies at our hands. We relinquish the labour; but it may not be altogether improper to hazard a reflection on the expediency of Britain aiding the efforts of the Arabs, under the new religion, to maintain and to embellish their independence. We cannot but regret that the friendly solicitations repeatedly addressed by the Wahabee powers to the government of Bombay have hitherto been totally disregarded. This we learn from the travels of Lord Valentia, to whom we are indebted for much of the information we possess of the curious transactions of these people. There was a period, certainly, within the times in which these applications were made, when no alliance with the Ottoman court could have been pleaded in excuse for such negligence. Nor do we conceive that any assistance, of the nature required by them, could at all, even during such an alliance, be construed into an infraction of it; though it were, the offence, we presume, would not entail any very formidable evils. The Arabs were surely entitled to the common respect generally paid to independent nations, however they may have contrived to be ranked among them, and have every right to wish and endeavour to promote their own welfare. This, we think, may be effected without injury to ourselves, probably with advantage. Here it may not be ill-timed to suggest, as some evidence of this opinion, the decided benefit which might have already resulted from a different line of policy than that which has been adopted. The indignation of Britain was lately poured out on some of the worse than savage monsters of the Barbary states, and all Europe joined in expectation of the completeness and rapidity of the retribution which should redeem her long and humiliating torpor. Would it not have been judicious to have previously obtained the good understanding of the Arabs, with whom they trade, and who, notwithstanding their participation in the traffic of human flesh, are accustomed to treat them, especially the Algerines, with the most sovereign contempt? We can have no doubts on the subject, nor can we hesitate to extend our views much farther, so as to anticipate a most salutary revolution in the affairs of the eastern world as the consequence of our interference.

ARABIC GUM, a gum which exudes from the *Mimosa Nilotica*, probably was thus denominated because it was originally imported from Arabia. See CHEMISTRY and MATERIA MEDICA.

ARABIS, Bastard Tower Mustard, a genus of plants belonging to the Tetradynamia class, and order Siliquosæ.

ARACAN, a region of Asia, on the bay of Bengal, which was subdued by the Birmans in 1783, and became a province of their empire; is bounded on the east by the Birman empire, and on the south by Pegu, and presents a diversified aspect of lakes, rivers, mountains, and plains. The soil in the flat country produces excellent rice, the richest fruits of tropical climates abound, and the mountainous pastures feed numerous herds of cattle. The buffaloe, the elephant, and the camel, are substituted for horses in the labours of agriculture, as well as for domestic purposes. The northern districts of Aracan, possessing a fine climate and a rich soil, are covered with opulent towns and populous villages; but the southern part is a wild and inaccessible desert, the undisturbed abode of tigers, buffaloes, and elephants. The natives are in a state of great barbarity and ignorance; and in religion and manners resemble the other uncivilized nations of the east. The Dutch and Portuguese formerly had a considerable trade with this country; but it is now transferred to resident Mahometan merchants, who exchange cloth, cotton, pepper, iron, steel, &c. for elephants, ivory, tin, stick-lac, and precious stones.

ARACAN, the capital of the province of the same name, occupies a remarkable spot on the banks of a river; is surrounded by lofty and rugged mountains, which form a natural fortification, through which the entrances and gates of the city are cut in the solid rock; and it is distant 50 miles from the sea. The population, now about 16,000, is said at one time to have been equal to 160,000; and the city was 15 miles in circuit, contained 600 temples, and a splendid palace, richly decorated with golden ornaments. The river, also called Aracan, traverses the city, and forms a most capacious harbour, which admits ships of the largest burden; but as the tide rises from 15 to 20 feet, the current of the stream is extremely rapid. N. Lat. 20°, 45.′ E. Long. 93°, 5′.

ARACHIS, Groundnut, a genus of plants belonging to the Diadelphia class.

ARACHNE, the inventress of the art of spinning and weaving, according to ancient mythology, was a maid of Lydia, and had reached such perfection that she ventured to become the rival of Minerva. The goddess of wisdom was offended at the presumption of a mortal, tore her work, and chastised her with blows. Driven to despair by this rude treatment and disgrace, she destroyed herself; but Minerva, regretting the violence, and moved by compassion, restored her to life, and transformed her into a spider, which still exercises the same trade.

ARACK, a spirituous liquor prepared by distillation in the East Indies. See ARRACK.

ARÆOMETER, from the Greek words signifying *rare* or *light*, and *measure*, is an instrument for determining the specific gravity of liquids, and is analogous to Hydrometer. See HYDROMETER.

ARÆOPAGUS. See AREOPAGUS.

ARAFAT, signifying *the mountain of knowledge*, is a mountain near Mecca, in Arabia, which is held in great veneration by the faithful. The Mahometans suppose that Adam and Eve, after their expulsion from paradise, and a separation of 120 years, met on this mountain; and part of the solemn devotions which are required of those who make the pilgrimage to Mecca, is performed on the ninth day of the last month of the Arabic year, on this sacred spot. With uncovered heads, and with every other expression of humility and mortification, they spend five hours of the evening of this day on the mountain; and having received the honourable appellation of *hadgis*, which is conferred by the priest, and belongs to those who have proved their piety by this extraordinary ceremony, they retire to Mecca.

ARAGON, a province in Spain. See ARRAGON.

ARAL, a lake, or inland sea of Independent Tartary, and 120 miles to the eastward of the Caspian sea, from which it is separated by an elevated plain, is above 100 miles in breadth, and more than 200 miles in length, from north to south. The western shores are high and rocky; and the rivers Sirr and Gihon, the ancient Iaxartes and Oxus, discharge their waters into this lake; and the same kinds of fish which frequent the Caspian, are found in it. Having no visible outlet, the waters are strongly impregnated with common salt, which is extracted by spontaneous evaporation. The *Lake of Eagles* is an appellation sometimes applied to lake Aral.

ARALIA, or ANGELICA TREE, a genus of plants belonging to the Pentandria class.

ARANEA, the spider, a genus of insects arranged under the Aptera order. See ENTOMOLOGY.

ARANJUEZ, a town in the province of New Castile in Spain, which has been selected as a residence of the royal family, occupies a charming spot on the banks of the Tagus, is about 20 miles from Madrid, and during the visit of the court in the spring season contains about 10,000 inhabitants. From an inconsiderable village, Aranjuez has been converted, in little more than half a century, into an elegant town, with spacious squares, broad streets, and fine houses. A magnificent church is erected in the principal square, which is also adorned with a splendid fountain for supplying the town with water. The amphitheatre, for the exhibition of bull fights, is a brick building, 160 feet in diameter. The palace, originally erected by Philip II. and improved by succeeding sovereigns, has nothing striking in its external aspect. Among its internal decorations are enumerated the Annunciation by Titian, and other excellent specimens of the productions of celebrated painters. But the royal gardens, watered by the Tagus, and unrivalled in extent and variety of scenery, exhibit the most splendid assemblage of all the beauties of nature and art.

ARAR, the modern Saone, a navigable river of Celtic Gaul, mentioned by Cæsar, and over which his soldiers built a bridge in a single day. The Arar joins the Rhone a little below Lyons.

ARARAT, a mountain of Armenia, on which it is supposed the ark of Noah rested after the diminution of the waters of the deluge. Numerous conjectures have been offered concerning the position of this mountain. According to some, it is one of the mountains which divide Armenia from Mesopotamia, and border on Assyria; but others describe mount Ararat as a detached mountain in the middle of Armenia, which, from an extensive plain, rears its double summit in the form of a sugar-loaf, and is covered with perpetual snow. Large masses of sandstone and loose sand compose the lower regions of the mountain; a few stunted shrubs include the whole of its vegetable productions; and on one side a deep chasm adds to the gloomy aspect of this sterile scene. See *Tournefort's Travels.*

ARATUS, a Greek poet, was a native of Cilicia, flourished about 270 years before the Christian era, and was the author of a poem entitled *Phænomena,* which contains a detail of the astronomical opinions of the ancient philosophers. This poem was translated by Cicero; but a fragment only of his translation has been preserved. A translation by Germanicus Cæsar, as well as the original poem, is yet extant; and the quotation of St Paul, in his address to the Athenians, "For we are also his offspring," (Acts xvii.) is from this poem of Aratus.

ARAU, or ARAW, a town of Switzerland, which stands on the right bank of the Aar. The inhabitants, amounting to about 2000, are chiefly employed in the manufacture of cotton stuffs, printed calicos, ribbons, cutlery ware, and in tanning. The soil of the surrounding territory is rich and fertile, and the scenery is picturesque and beautiful.

ARAUCANIA, a territory of South America, extending along the shores of the Pacific ocean about 200 miles southward, from nearly the 37th degree of south latitude, and stretching more than 400 miles inland towards the Andes, the lower regions of which are included within its limits. The face of the country is variegated with extensive plains, some parts of which are distinguished by their fertility and luxuriance of vegetation, mountainous districts, the loftier parts of which are covered with perpetual snow, thick forests, and spacious lakes.

The inhabitants of Araucania are a warlike race, and have successfully resisted every attempt of the Spaniards to reduce them to subjection. Retaining all their primæval manners and customs, they seem to have made scarcely any progress in civilization since they were first known to the adventurers from the Old World; but they have been singularly fortunate in having historians who, with little discrimination, ascribe to them great wisdom and intelligence in arts, religious sentiments, and political establishments. Even the term Science has been preposterously applied to the very simple attainments of a rude and barbarous people. They have no written language; they believe, it is said, in one Supreme Being, but they have subordinate deities, and especially a god of war, which is quite characteristic of those feelings which their mode of life is most apt to excite. Their government is somewhat of a republican form; they live in scattered villages; their food is chiefly vegetables, as potatoes and corn, but, when opportunity offers, they indulge in drunkenness; their medical knowledge, which has been dignified with the name of science, is limited to magical incantations; and a modern anatomist would surely smile when he is told, that a people, whose only lancet is a sharp flint fastened to a stick, have some skill in dissection. In their marriages, the destined wife is carried off by force, and polygamy is only limited by the means of support; and human sacrifices, usually prisoners taken in war, are offered to their deities. With all the vices of a rude people, the Araucanians possess none of the virtues which entitle them to the extravagant praise which they have received. Their chief manufacture is the *poncho,* or cloak, made of the wool of the *Llama,* or Peruvian sheep, and some of them are of a very fine quality, and bring a high price. These cloaks form a considerable branch of trade with the Spaniards; and it is conducted chiefly by barter.

ARAXES, now ARAS, a river which forms the boundary between Armenia and Media, has its sources in mount Caucasus, is remarkable for the impetuosity of its current, and after a course of 500 miles falls into the Caspian sea. It is subject to inundations in summer, from the melting of the snows in the elevated regions from which its waters are supplied.

ARBA, or ARBE, an island in the Adriatic sea, and lying in the gulf of Carnaro, is about 30 miles in circuit, and is annexed to the Austrian territory. It produces corn, wine, and oil; and large quantities of firewood are exported to Venice. Sheep, hogs, and a good breed of horses, are reared, and, with wool, silk, tunny, and mackerel fisheries, form a considerable trade. The whole population is estimated at 3000, of which 1000 occupy a city of the same name, which stands on a peninsular eminence between two harbours.

ARBELA, now Irbil, a city of Assyria, whose name has been transmitted to posterity along with the record of the celebrated and decisive victory which Alexander the Great obtained over Darius, whose army, it is said, amounted to the unwieldy force of 600,000 men, while that of the Macedonian hero was not equal to 50,000. The conqueror lost only 500 men; but 40,000 of the Persians were left dead on the field.

ARBITER, a person chosen by consent of parties, according to the practice of the civil and Scots law, who is authorised to perform the duties of a judge in deciding differences. The office of arbiter being voluntary, no person could be forced to undertake it; but having once accepted, he might, by the Roman law, be compelled to pronounce a decision. Arbiters have no legal jurisdiction, and therefore cannot order witnesses to give evidence, or the production of written deeds; but this power is supplied by the Court of Session in Scotland, who grant warrants for such purposes, on the application of either of the parties, or of the arbiters themselves. When the authority entrusted to arbiters to determine any case is limited to a fixed period, no judgment pronounced after that time is binding; but when the award or decreet-arbitral is conformed in all respects to the terms of the submission, unless fraud or corruption be alleged and proved, it is final, and not subject to the review of any court. If two arbiters be chosen, and they do not agree in their award, they have sometimes the power of naming an umpire, whose sole decree is equally valid with the original arbiters.

ARBITRATOR, is generally synonymous with arbiter; but the civil law makes some distinction. The arbiter, it is understood, decides according to the rules and practice of law; but the arbitrator judges in the case according to his own discretion, or as he is guided by the principles of equity.

ARBOIS, a town in the department of Jura in France, which has a population exceeding 6000, and has been long famous for its white wines, which are a very considerable source of trade, and are well known throughout the kingdom.

ARBUTHNOT, John, a learned physician and miscellaneous writer, was born near Montrose in Scotland about the commencement of the reign of Charles II. was educated at the university of Aberdeen; and having been admitted to a degree in medicine, he removed to London, where, it is said, he taught for some time mathematics, in which he had risen to considerable eminence. But while he occupied his literary industry, which seems to have been always active, in various investigations, he made rapid advances in professional employment and reputation. He was first appointed physician to Prince George of Denmark, and afterwards physician in ordinary to Queen Anne; and although, on the death of the Queen, his connexion with the court was dissolved, his medical practice continued extensive and lucrative to the end of his life.

Dr Arbuthnot flourished during the bright era of English literature, and was one of that constellation of wits which shed an unfading lustre on the annals of their country. He was the intimate friend and associate of Pope, and Swift, and Gay. No man possessed more varied talents than Dr Arbuthnot. His "Examination of Woodward's Account of the Deluge," his "Treatise on the Usefulness of Mathematical Knowledge," his "Tables of Ancient Coins," &c. and two works immediately connected with his own profession, "On Aliments," and "The Effects of Air on Human Bodies," afford ample proof of his learning and medical knowledge; his talents for wit and humour are abundantly conspicuous in the "History of John Bull," those parts of the "Memoirs of Martinus Scriblerus" which relate to anatomy, and delineate ancient manners and customs, and "A Treatise concerning the Scolding of the Ancients," and the "Art of Political Lying;" but it is alleged that the delicacy of his satire is not always free from asperity, especially when the influence of party spirit prevailed, as in his attack on Bishop Burnet, his political opponent, and in the bitter invectives in the famous "Epitaph on Colonel Charteris." But, independent of his own literary labours, the name of Arbuthnot, as it is commemorated by his distinguished friends and associates, will be transmitted to posterity along with their works. Pope has addressed to him the "The Prologue to the Satires;" and Swift, who said of him, "that he has more wit than we all have, and his humanity is equal to his wit," has eulogised his knowledge and benevolence;

> "Far from his kind Arbuthnot's aid,
> Who knows his art, but not his trade."

A severe asthma, which induced a dropsical affection, terminated his life in London in February 1735. Distinguished by his attainments in science and literature, he was not less eminent for integrity, benevolence, and piety.

ARBUTUS, or Strawberry-tree, a genus of plants belonging to the Decandria class, one species of which, *arbutus unedo*, a beautiful evergreen shrub, is a native of the western districts of Ireland, and is a fine ornament to the picturesque scenery of the lake of Killarney.

ARC, Joan of, better known by the name of the *Maid of Orleans*, acted a conspicuous part in France, in one of the severe struggles against the English invaders, and was born about the beginning of the 15th century. While in her 27th year, and in the humble capacity of servant at an inn in the village of Domremi, the disastrous fate of her country had made a strong impression on her mind; and fancying that she was commissioned by heaven to be the deliverer of the kingdom, under this enthusiasm she appeared before the governor of Vaucouleurs, who presented her to the French court; and when she was introduced to the king, she declared, in the name of the Supreme Creator, that she would raise the siege of Orleans, and conduct him to Rheims to be crowned. Her extraordinary enthusiasm was variously regarded. While some doubted the reality of her mission, a council of divines and learned men pronounced her inspiration to be supernatural; and the superstition of the times, or the sagacity of individuals, employed her as a fit instrument to rouse the drooping energies of her country. Arrayed in military attire, and displaying a consecrated banner, she headed an army sent to the relief of Orleans, entered the place with a convoy, and successfully attacked the English, who were panic struck, and precipitately raised the siege. After various successes, she proposed to proceed to Rheims, to perform the other part of her mission. The attempt was full of hazard, but she had now inspired unbounded confidence, and no enterprise, however arduous, was dreaded. With an army of 12,000 men she marched towards Rheims, which, as well as the country through which she passed, was then in the hands of the English, but their progress was unmolested; the enemy fled before them, and the keys of the city were presented on their arrival; the king was crowned and anointed; and as a mark of royal favour for her extraordinary services, her family was ennobled.

The Maid, having accomplished her mission, was desirous of retiring to her own proper station; but the French general, aware of the importance of her services, encouraged her to remain in arms till the final expulsion of the enemy. She threw herself into Compeigne, which was closely besieged; the garrison thought themselves invincible in her presence; but in an unfortunate sally she was taken prisoner. Her fate was now sealed. Loaded with irons she was carried to Rouen; and under the authority of the Duke of Bedford, regent of the kingdom, she was charged before an ecclesiastical court with impiety and sorcery; and being convicted, she was condemned to the flames, and suffered that unjust and cruel punishment, which was dictated partly by the superstition and partly by the barbarity of the times, in 1435.

The short but eventful story of the Maid of Orleans, has been the subject of various works both in prose and verse. Voltaire and Chapelaine have delineated her heroical exploits in French verse; and more lately, Mr Southey, a bard of our own country, has wrought up the adventures of Joan of Arc into an epic poem.

ARCA, or Ark-Shell, a genus of bivalve shells. See Conchology.

ARCADE, denotes any opening in a building which is formed by an arch.

ARCADIA, a mountainous district of Peloponesus, which occupies the central parts of that peninsula. The face of the country is uneven and rugged; it is watered by numerous streams; the more elevated regions are clothed with verdant herbage, and the soil of the vallies is rich and fertile. Corn has been sometimes raised; and the vine and the olive are enumerated among its spontaneous productions; but flocks and herds have always constituted the chief wealth of the Arcadians. In the early history of Greece, Arcadia holds a conspicuous place; and her sons have never failed to distinguish themselves by their prowess in defence of their own liberties or in the general cause.

Arcadia may be regarded as the native scene of pastoral poetry, and of many of the incidents of ancient mythology. The rivers flow in numbers, and

"Not a mountain rears its head unsung."

Cyllene, Erymanthus, Olympus, and Stymphalus, are familiar to every classical reader. The celebrated Styx is one of the rivers of Arcadia. The coldness and noxious quality of its waters diffused the chill of death over every living thing that tasted or approached them; and no oath was held more sacred among gods and men than when it was solemnly sanctioned by this stream.

ARCESILAUS, a Greek philosopher, who flourished about 300 years before the Christian era; was the disciple of Aristotle, Theophrastus, and Cantor, at Athens, and the founder of the *second school*, or *middle academy*. Science, according to Plato, should be directed, not to external objects which affect the senses, but to the pure objects of intellect, as they have existed as ideas or forms in the divine mind from all eternity. The inference from this doctrine shewed that no certain knowledge could be obtained from sensible objects. But Arcesilaus proceeded farther, and maintained, that every thing is uncertain to the human understanding. Truth and error have no distinctive characteristics; and the powers of man furnish him only with probable reasonings and opinions, but which, he admitted, are sufficiently calculated to guide him in the ordinary affairs of life.

ARCH, any part of the circumference of a circle or curved line.

ARCH, a mode of constructing buildings. See Architecture.

ARCHANGEL, a considerable town, and capital of a province of the same name, in the northern part of the Russian empire, stands on the eastern bank of the river Dwina, which discharges its waters into the White sea, and is described as three miles in length and about a mile in breadth. The streets are in general narrow, and the houses are chiefly built of wood. The town-house is a substantial structure of hewn stone, and consists of three stories. In the more flourishing periods of its history, Archangel reckoned 30,000 inhabitants, but the number at present is not estimated higher than six or seven thousand.

Archangel was discovered by the English in 1553, in an expedition under Sir Hugh Willoughby, which was sent out to explore a passage by the north of Europe to China and the East Indies. The only ship belonging to the expedition which escaped the rigors of a northern winter, had taken shelter in a bay near the spot on which Archangel was afterwards built. Captain Chancellor, the commander, was hospitably received by the Russians, invited to Moscow, and honourably entertained, and entered into a treaty which conferred upon the English the high exclusive privilege of trading in all parts of the Russian territory, free of every kind of duties. Archangel rose into importance, became the emporium of Russia, and of a lucrative commerce to the English, and continued to enjoy its full share of prosperity, with some slight interruptions from the commercial interference of the Dutch, till Petersburgh became the seat of the imperial government, and the commencement of the Baltic trade. In the flourishing period of the history of Archangel, an annual fair was held in August, at which assembled merchants from every part of that wide empire, to meet the English and other traders, from whom they purchased by barter, or for money, broad cloths, linens, silk and woollen stuffs, paper, lace, toys, cutting instruments, and colonial produce, and gave in exchange tallow, hides, feathers, yarn, silk from China and Persia, furs, bristles, caviar, rhubarb, potash, iron, corn, lintseed, and flax.

Many of the commodities above enumerated have found less circuitous channels, and, being withdrawn from Archangel, have greatly diminished its prosperity. But it is still the seat of trade for the productions of the northern and western parts of Siberia, from which valuable furs and abundance of iron are obtained; and the fisheries of the White sea and the Frozen ocean furnish large quantities of stock-fish to be added to its imports. N. Lat. 64° 34′. and E. Long. 39°.

ARCHBISHOP, a church dignitary of the highest order, was not known in the east till the year 320, and was at first only a personal title of distinction, conferred as a mark of respect on the bishops of large cities. At a later period archbishops became metropolitans, and had jurisdiction assigned to them. Four orders, or degrees, which were afterwards introduced, namely *patriarchs*, *archbishops*, *metropolitans*, and *bishops*, composed the ecclesiastical hierarchy. In Italy, and some other parts of the continent, the distinction between metropolitan and archbishop still exists. The latter often holds the title, but without the authority and jurisdiction which always belong to the former. Beside the superintendence of the bishops and clergy of his own province, the archbishop exercises episcopal jurisdiction in his own diocese.

The ecclesiastical government of England is divided into two provinces, Canterbury and York. The archbishop of Canterbury is styled *primate* of all England; previously to the year 1152 his jurisdiction extended to Ireland, and it is supposed included Scotland and the isles. He is the first peer of the realm, takes precedence next to the royal family, and it belongs to him to crown the sovereigns of England. Austin, appointed by King Ethelbert in 598, was the first who filled this see. The archbishop of York is next in ecclesiastical dignity, has precedence of all dukes not of the blood royal, and excepting the Lord Chancellor, of all the great officers of state, and he has the privilege of crowning the queen-consort. Paulinus was the first archbishop of York, and he was appointed by Pope Gregory in 622.

The ecclesiastical establishment of Ireland consists of four archbishops, namely, Armagh, to which the primacy is annexed, Dublin, Cashel, and Tuam. While the episcopal form of church government existed in Scotland, St Andrews and Glasgow were archbishoprics. The former was invested with the authority of metropolitan in 1470 by Pope Sextus IV.

ARCHDEACON, a dignitary in the church of England, next in rank to the bishop. The archdeacons of England amount to sixty.

ARCHELAUS, a Greek philosopher, who flourished about 440 years before the Christian era. He was the last teacher of the original Ionic school, which he removed to Athens, acquired great celebrity, and was the master of Socrates. He taught that a double principle exists in all things, namely, the *expansion* and *condensation* of the air; that heat is ever in motion, and is the cause of action, and that cold is always at rest. He ascribed infinity to the universe, supposed that the earth, originally a chaotic mass of moist matter, assumed, when dried, an ovate form, and asserted that all living creatures were produced from its heat. In morality, it is said, he maintained that nature had made no distinction between right and wrong, that all actions are indifferent in themselves, and the character of good or evil is marked only by positive institutions.

ARCHERY is the art of shooting with a bow and arrow. The origin of this art is undoubtedly coeval with the earliest period of the history of most nations. It is particularly mentioned in Sacred history; and the Persians, the Ethiopians, the Egyptians, and Scythians, but especially the latter people, were celebrated for the practice of archery. Among the Greeks the bow was early employed as an implement of war; and the Romans, in a later period of their history, successfully adopted the same instrument. The Goths, the Vandals, and the Huns, were in no small degree indebted to the use of the bow and arrow for their rapid progress and victorious career.

The use of the bow, it is supposed, was unknown in Britain till about the period of the Saxon invasion. But in England archery afterwards attained a high degree of perfection. The famous battles of Cressy, Poictiers, and Agincourt, were won by the skill and prowess of the English archers. The English government liberally encouraged archery, and numerous statutes, some of which were passed even after the introduction of fire-arms, were enacted for the regulation of the practice; and it is curious to observe that, as late as the time of Elizabeth, and even later, treatises were published in which the bow is preferred to the musket as a military instrument.

Archery was not neglected in Scotland. An act of James I. required all males to practise the art; but it is generally admitted that the Scots were inferior to their southern neighbours in the use of the bow. The battles of Homildon and Flodden, so fatal to Scotland, were decided in favour of the English by the strength and skill of their archers.

Archery is now known in Britain only as an active and agreeable amusement. Three associations exist in England for its practice, under the name of *The Kentish Bowmen; The Woodmen of Arden;* and *The Toxophilites.* In Scotland two societies are instituted for the same purpose: *The Royal Company of Archers*, at Edinburgh, which is supposed to date its origin in the time of James I., was incorporated by a charter from Queen Anne; and *The Kilwinning Society of Archers* has long held an annual meeting, which is well known in Ayrshire by the name of Papingoe. Some of the members of these societies possess considerable dexterity and skill in the use of the bow and arrow.

ARCHETYPE is the first model of a work according to which others are constructed. In the language of the mint, the same term is applied to the standard weight by which others are adjusted.

ARCHÆUS, signifying *principal, chief, or first mover*, is a term applied, by Van Helmont, to an imaginary being which he supposed presided over the animal economy for its preservation. The place assigned for the residence of the Archæus was the entrance into the stomach.

ARCHIL, a colouring substance which is procured from certain species of lichen, and especially lichen *rocella* and *parellus*, which are brought from the Canary and Cape de Verd Islands. The colour is a rich purple; and in its preparation it is bruised, moistened with urine mixed with quicklime, and having undergone fermentation, is dried and formed into a hard paste. In this state it is called *litmus*. Archil is employed by dyers to heighten their colours, and the litmus is used as a chemical test.

ARCHIMANDRITE, in the ancient Christian church, seems to have been nearly synonymous with abbot.

ARCHIMEDES, one of the most celebrated of the ancient philosophers for his attainments in mathematics and mechanical science, was a native of Syracuse, and was born about 280 years before the Christian era. He began early to devote himself to his favourite pursuits, travelled to Egypt to improve and extend his knowledge, and even, it is said, by the power and vigour of his genius, reflected lustre on the bright day of learning which then illuminated the regions of the east. Returning to his own country, he resumed the prosecution of those profound investigations of which the fragments are sufficient to render his name immortal.

The close of the life of Archimedes is almost the only event which the scanty biography of the philosopher can commemorate, and this too, had it been less connected with public transactions, might have been wholly obliterated from human records. In a war between Hiero, king of Syracuse, and the Romans, Syracuse was closely besieged; and by the inventions of Archimedes, the accounts of which are probably exaggerated, when it is said that he set the ships of the enemy on fire by means of reflectors, and, when they approached nearer, dragged them out of the water by engines, the most vigorous efforts of the Roman power were long frustrated; but the city was taken by storm, and Archimedes, intent on a geometrical investigation, and ignorant of what had happened, was put to death by a soldier; although it is reported that Marcellus, the Roman general, had issued strict orders to save the philosopher and to protect his house from plunder. Marcellus was deeply grieved at his disastrous fate; and, as an act of retribution, conferred signal favours on the relatives of Archimedes, honoured his memory with a splendid funeral, and ordered a tomb to be erected, on which, as the philosopher had desired, a sphere inscribed in a cylinder, alluding to his beautiful discovery, was sculptured. The death of Archimedes happened 212 years before the Christian era. After the lapse of 140 years, Cicero visited the tomb of the Syracusan philosopher. No memorial of it then remained in the minds of his countrymen; but, after a diligent search, the top of a column rising from a close thicket of thorns and briars was discovered; and the sphere and cylinder, which time had spared, marked it as the tomb of Archimedes.

The discovery of the method of determining the specific gravity of bodies, which, it is said, he made while bathing, is ascribed to Archimedes; his knowledge of the power of the lever is illustrated by the famous apophthegm, " Give me a place to rest upon and I shall move the earth;" and the screw for raising water, which is distinguished by his name, the spiral screw, the system of pulleys, and various compound machines for raising weights, are enumerated among his inventions. The works of Archimedes yet extant, are, " On the Sphere and Cylinder;" " On the Dimension of the Circle;" " On Conoids and Spheroids;" " On Spiral Lines;" " On the Quadrature of the Parabola;" " On Floating Bodies," &c. A splendid edition of his works was published at Oxford in 1792.

ARCHIPELAGO, a general appellation for a sea interrupted with islands, was originally limited to the Ægean sea between Asia and Europe, but is now extended to any sea divided or broken by numerous islands.

ARCHITECTURE.

Architecture, or, the Art of Building, is divided into three branches, denominated from the purposes to which they are respectively applied—Civil, Military, and Naval. It is the first only, which is usually, for the sake of distinction, called Architecture, that is to be the subject of this treatise. Our view of it will comprehend its most general principles, considered both as a mechanical science and a fine art. We propose, accordingly, to speak,

I. Of the Materials used in Architecture. II. Of the Principles of Construction. III. Of Style, or the Production of Effect. And we shall conclude with a short history of its origin and progress.

Architecture

PART I. OF MATERIALS.

In treating of the materials which are usually employed for architectural purposes, two things are to be considered,—1. The kinds and qualities of materials; and, 2dly, Their mechanical strength.

Chap. I. Of the Kinds and Qualities of Materials.

Materials may be divided into Constructive, Uniting, and Ornamental.

SECT. I. *Of Constructive Materials.*

Constructive materials are timber, stone, brick, earth including clay and turf, slates, tiles, thatch, &c. some of the metals, and glass.

Timber.—Trees, even in their rudest state, or with little alteration, are convertible into defences against the weather and the attacks of wild beasts. The early inhabitants of some countries used no other materials. But it is not this primitive architecture that we are to contemplate. The term *timber* is applied to such trees as admit of being cut into planks and posts, in which condition chiefly they are employed in modern times and civilized countries.

Different trees have different natures, and timber, consequently, is of various qualities. Those principally required are magnitude, cohesion of fibres, the capacity of being wrought, and durability. That timber which has these qualities in greatest perfection, is of course most valuable. In general, the gifts and advantages of nature being in some degree qualified, it is necessary to compound between them; and the consideration of expense, dependent on the plenty or scarcity of the kinds of timber, is an important matter in the builder's calculation. We may notice a few particulars respecting certain species used in this country.

Fir is plentiful, may be had of great magnitude, and is easily wrought. Oak surpasses it in absolute strength and durability, but is dearer, and demands more labour. Beech is a close compact wood, soon injured by moisture. Ash affords a neat, tough, and conveniently worked timber, but does not stand the weather well. The chief excellence of elm is its bearing to be pierced or bored with nails and bolts, better, perhaps, than any other wood, but it is extremely liable to shrink and warp, and is very cross-grained, so that it cannot safely be trusted. Spanish chesnut has some of the characters of oak. Lime, sycamore, and poplar, partake of the imperfections of beech. Memel fir is, perhaps, on the whole, the most eligible timber for the ordinary purposes of builders.

Stone.—This is the general name for all the earthy minerals employed in building, such as sandstone, granite, porphyry, whin, lime-stone or marble, flint, &c. These also have different qualities, and are consequently of greater or less value.

Sand-stone.—Sand-stone is usually found in flat pieces, of variable but seldom very great thickness, so that it needs only to be cut transversely, in order to afford suitable sizes and shapes. This is easily done when it is soft, but excess of softness is obviously an essential fault. The contrary extreme is rarely met with in sand-stone, and can scarcely be objected to when it is, unless where labour is very dear. The upper beds of the quarry are generally softest, and the hardness increases rapidly with the depth. To this remark, however, there are many exceptions. Some sand-stone becomes hard by exposure to the atmosphere, as that found near Bath. The abundance of good sand-stone in its vicinity, has contributed to the beauty of New Edinburgh. That procured at Craig-Leith quarry, a little to the north-west of the town, has been long famed, and is in demand at London, Gottenburgh, and other distant places.

Granite.—When the constituent parts of granite are pretty uniformly mixed, it is much esteemed for building purposes. It generally possesses very great strength, is found in very large masses, and has often a pleasing variety of colour, but with rather too much of a sparkling appearance. The town of Aberdeen is built of a granite, some of which has lately been introduced into London for its strength and durability, so requisite in some parts of bridge building.

Porphyry.—Porphyry is often confounded with granite. The name applies to a vast variety of stones occasionally used. Whin, or greenstone, a very abundant production in many countries, is extremely durable, and may be readily dressed with the hammer. It is employed for coarse walls and inside work, being commonly too dark for shew; in Scotland, where it is very plentiful, the roads and streets are paved with it. Clinkstone, basalt, and some other stones, found in similar situations, may be ranked with whin.

Limestone—has very diversified appearances and qualities. When it is hard, as in the marble of some countries, and when the conversion of it into lime is not thought to be of greater moment, it is employed in building. It dresses well, and is easily divided.

Flint,—or siliceous stone, is commonly so hard and so difficult of receiving form, that it is rarely used in this art on the large scale. But small flints may be advantageously had recourse to in some cases. The method of using them, recommended in Mr Atkinson's Views of Cottages, &c. deserves notice. It is very similar to the process of raising Pisa walls.

Objection to stone.—An important objection to many sorts of stone is their great power of conducting heat. It is most remarkable in those that are very dense and compact, as whinstone. In consequence of it, plaster does not adhere well to them, and they have a cold, raw, or moist feel. The vulgar notion is, that these stones contain water, which they give out in peculiar conditions of the weather; but the fact is to be explained on a chemical principle, viz. the abstraction of heat from the adjoining air occasioning a deposition of the vapour that had been dissolved in it. The condensation of moisture on the windows of a crowded room during cold weather, is a phenomenon of a similar nature. The best remedy, perhaps, or rather defence against the evil, consists in separating the lathing from the walls for some distance, and filling up the intervals with some bad conductor, such as dry earth, sand, brick-dust. There are few cases in which this practice would not be found highly conducive to comfort.

Roasting the stones, which some have proposed, even if any way consistent with time and economy, will not alter their nature, unless carried to a very high degree, and therefore cannot be generally recommended.

Bricks.—In many respects this is a better material than stone; and the objection which has sometimes been made to it, namely, its want of durability, applies rather to the particular manufacture than to the substance itself. Bricks may be made to vie with stone in this very quality, and even claim the preference which an Egyptian monarch, spoken of by Herodotus, seems to have given them. "This prince," says that historian, "desirous of surpassing all his predecessors, left, as a monument of his fame, a pyramid of brick, with this inscription on a piece of marble: "Do not disparage my worth by comparing me to those pyramids composed of stone; I am as much superior to them as Jove is to the rest of the deities; I am formed of bricks, which were made of mud, adhering to poles, drawn from the bottom of the lake." Beloe's *Herod. Euterpe*, 136. This very pyramid, noticed both by Norden and Pococke, is situate about four leagues from Cairo. It is the only one that is built of these substances, which are understood to have been sun-dried; but it bids fair to last as long as any of those wonderful fabrics.

In this climate, probably, we have not sun enough to convert clay into bricks within a reasonable time. Artificial heat is, accordingly, almost constantly applied to it. This renders the material costly, especially where coal or other fuel is scarce. Bricks are much more easily arranged, occupy less space, and are lighter for carriage than stones, but are liable to several imperfections, arising from the inadvertencies and mismanagement of workmen.

Earth, &c.—Earth, including clay and turf, is now seldom ranked amongst constructive materials, where the science is well established. They are occasionally used, however, especially in country places, and are the rather noticed here, because we wished for an opportunity of stating some useful remarks of Mr Atkinson's on the construction of mud-walls for cottages. These when well made are very durable. The skeleton of the cottage, which is first formed, consists of upright pieces of timber, about four inches square, placed at the distance of 15 inches from each other, and bound together by horizontal pieces for the support of the roof and floors. Strong plastering laths are then nailed horizontally across the upright pieces, on which the mud or plaster properly mixed with chopped straw, is to be laid with a trowel. When this has become dry, a thin outside covering of lime and sand is to be applied over it; and the inside of the building, which is to be lathed in the same manner, may be covered with mud, or with lime and hair. Those mud walls are said to be best which are composed of clay and a large portion of sand in rather a coarse state.

Pisa walls.—Here, too, we may describe the nature of Pisa walls, so called because much used in the city of that name. The foundation is either of brick or stone raised about two feet from the ground. On this is fastened, by means of wedges, a sort of wooden case, containing the common earth of the fields, very hard pressed down. This case is moved always upwards as the work proceeds, and the wall when dry, is covered with lime and sand. It is a a process like this that is recommended by Mr Atkinson from small flints, as formerly mentioned. These, as existing in gravel, and combined with mortar, are used in place of the earth put into the frame. It is convenient to know the practibility and efficiency of such means, as cases may occur to require their adoption.

Slate, Tile, &c.—These materials are confined to the construction of the roofs of houses, of which they form that part which is exposed to the weather. They are not all equally suitable to the purpose, but the selection is generally determined by local circumstances and prejudices.

Metals and Glass.—Lead and copper, besides occasional uses in building, are sometimes substituted for the substances now mentioned, as roofing materials. Iron is still more extensively employed, and every day discovers additional proofs of its subserviency to the purposes of the builder. In carpentry, an important branch of architecture, it has been long applied to the offices of king and queen posts, straps, &c. for roofs. Modern artists have introduced it into the construction of windows, stairs, floors, &c. with decided advantages where great strength is required, and especially where there is unusual hazard of fire. The finest examples of its value, as a constructive material, is to be seen in cast iron bridges, those splendid monuments of modern ingenuity.

Glass is entirely confined to the structure of windows for the admission of light. It is of various qualities and denominations, as plate-glass, crown-glass, German glass, &c. In some countries, where the manufacture of glass is unknown, or where it cannot conveniently be procured, a substitute for it has been found in talc, mica, some sorts of shells, &c. &c. no way, however, comparable to it in properties.

Sect. II. *Uniting Materials.*

The terms *Cement*, *Mortar*, *Tarras*, in masonry, are often used synonymously. But it would be convenient to restrict each to a distinct composition, viz. the first to such uniting materials as are employed in a liquid state,—the second to the merely soft mixtures of similar ingredients—and the last to those of a still more compound nature, used in aquatic buildings. As we cannot reasonably, however, expect to modify the current language, we must of necessity continue to speak as others have done before us.

Nature of mortar.—The chief and essential ingredient in cement is lime, not, indeed, in its natural state, but after having undergone the process of burning. So long as limestone contains fixed air or carbonic acid, it is unfit for cement; and, all other circumstances being alike, that lime which has been most effectually submitted to the action of fire, by which the fixed air is driven off from it, is most serviceable for the purpose. Now, as it is proved by experiment, that lime, after this treatment, gradually re-combines with fixed air if exposed to the atmosphere, an obvious precaution is suggested, viz. that of preserving it covered with sand or earth, &c. when not immediately in use; and on the same principle, it cannot be too powerfully inculcated on those concerned, that the sooner they use lime after it is burnt, the greater is the chance of its obtaining its advantages. The inattention of workmen to this important fact, is often so gross as to justify the strongest censure, because the infallible consequence is the speedy destruction of the building. To them, perhaps, it is quite unimportant whether the stones be cemented or not, provided they have laid in a sufficient quantity of what is supposed to answer the design. But the owner is certainly interested to have a durable fabric, and a conscientious artificer will study something else than the mere appearance of his materials.

It can hardly be said that the ancients had better ingredients for the composition of their cements, and yet it seems certain that their buildings bid fairer for prolonged existence, even commencing with the present time, than the generality of those which are now erected. Or if it be admitted that they had, still we must confess that they derived their superiority chiefly from their greater circumspection and industry. Here we cannot refrain from availing ourselves of the words of an experienced observer, who has done so much for the improvement of the arts of building in this country; we allude to Mr Peter Nicholson, from whose Architectural Dictionary we quote the following passage: "The practice of our modern builders is to spare their labour, and to increase the quantity of materials they produce, without any regard to its goodness; the badness of our modern mortar is to be attributed both to the faulty nature of the materials, and to the slovenly and hasty methods of using it. This is remarkably instanced in London, where the lime employed is chalk lime, indifferently burnt, conveyed from Essex or Kent, a distance of ten or twenty miles, then kept many days without any precaution to prevent the access of external air. Now, in the course of this time, it has absorbed so much carbonic acid as nearly to lose its cementing properties; and though chalk-lime is equally good with the hardest limestone, when thoroughly burned, yet, by this treatment, when it is slaked, it falls into a thin powder, and the core, or unburned lumps, are ground down, and mixed up in the mortar, and not rejected as it ought to be. The sand is equally defective, consisting of small globular grains, containing a large proportion of clay, which prevents it from drying and attaining the necessary degree of hardness. These materials being compounded in the most hasty manner, and beat up with water in this imperfect state, cannot fail of producing a crumbling and bad mortar; and, to complete the miserable composition, screened rubbish, and the scraping of roads, are thrown in as substitutes for pure sand. How very different was the practice of the Romans! The lime which they employed was perfectly burnt, the sand sharp, clean and large grained; when these ingredients were mixed in due proportion with a small quantity of water, the mass was put into a wooden mortar, and beaten with a heavy wooden or iron pestle, till the composition adhered to the mortar; being thus far prepared, they kept it till it was at least three years old. The beating of mortar is of the utmost consequence to its durability, and it would appear that the effect produced by it is owing to something more than a mere mechanical mixture."

In Scotland, generally speaking, there can be no excuse for the rapidity with which walls moulder down. We have lime of excellent quality, the mode of burning it is thoroughly understood and generally well practised, and sand and pebbles of all sorts may commonly be had at little expence. We shall not, then, be thought either disposed to cavil, if we assert that there is a blameable inattention to several important particulars, or officious, by taking it upon us to suggest the necessity and benefit of greater caution. Attention to the following directions, we have no doubt, will insure durability and firmness.

Directions for its preparation.—In the first place, let the lime, whatever be its quality, whether common limestone, chalk, or marble, be sufficiently burnt. This it is the interest as well as the duty of the builder to see into, and he is not warranted in committing the fact to the assertions of the people of the kiln whence it comes, or to the notions of his own subordinate agents. Secondly, let it be as soon as possible put into use, or, at least, covered from the air till it is so. If it is to be brought from a distance, it ought to be conveyed in close carts; waggons, or proper vessels, or, at all events, be furnished with some screen, as matting, straw, &c. not in shallow, wide, and unsheltered vehicles, nor late on *Saturdays*, when it will almost infallibly be left unprotected for at least thirty hours. Thirdly, Having immediately slaked it, let the proper proportion of clean large grained sand be mixed with it, adding no more water than is barely necessary for working it, which is to be done as already mentioned. And here we ought to say a word or two about the quality and proportion of sand to be used. That which is large and sharp, so as to prick the hands when rubbed, having no earth or mud mixed with it, which can be easily discovered by washing some of it in water for a trial, is to be preferred. Fossil-sand dries sooner than what is taken from rivers, and is fitter therefore for outside work, where it is of consequence to effect a speedy consolidation; but it is apt, if long exposed to the air before being used, to become somewhat earthy, which is alway a fault. A white sand is generally very smooth, and consequently not good; for the same reason, sea-sand, which has been subjected to a rolling motion, and is of course smooth, is not eligible. The proportion of sand must be varied according to the precise object in view; sometimes, three parts to two of lime; at others, equal parts of each; whilst, according to Vitruvius, three parts of pit-sand and two of river-sand may be used with one of lime. Wherever this last proportion can be adopted, it is obvious that the quality of the lime is greatly confided in. Lastly, let the mortar be kept well covered up for some considerable time before being laid on; and before using it, have it thoroughly beaten over again.

Improved Mortar.—Considerable attention has been paid of late years to the improvement of cements; and, in consequence, several very useful processes have been discovered The addition of bone-ashes, wood-ashes or charcoal, cellular or compact basalt in the state of powder, lime itself in the state of powder, and a great variety of other substances, to certain proportions of the other ingredients, is ascertained to promote their cementing power. What is called Loriot-mortar, from a Frenchman who discovered it, is of much efficacy. It consists in the addition of one-fourth or one-sixth part of powdered quicklime to the common mortar, only prepared a little thinner than usual. This compound, a few minutes after being made, acquires the consistence of plaster of Paris, and in a few days becomes as dry as ordinary mortar at the end of some months. As a water-cement, which requires speedy drying and firming, this mortar is extremely valuable. The tarras, or trass mortar of the Dutch, long used by them for the mounds and other works by which they have succeeded in protecting their low lands from the inroads of the ocean, is no way inferior to this composition. It is made by mixing the substance called *wakke*, or cellular basalt, reduced by grinding to the state of coarse sand, with the blue argillaceous lime that is got on the banks of the Scheldt. The process is quite a simple one. As much quicklime as will be needed in a week is spread in a kind of bason, to the thickness of about a foot, and sprinkled with water; then a stratum of tarras, such as above described, is laid over it to the same depth, and allowed to remain for two or three days, when the whole is beaten and mixed together, and again left for as long a time. It is now fit for building, and only requires to be well beaten when about to be used. The tarras has been imported from Holland into Britain for the sake of its efficacy. But this is expensive, and perhaps not altogether indispensable, as, according to Mr Nicholson, common basalt, provided it be calcined, will answer the purpose. This gentleman specifies the Calton-hill at Edinburgh as chiefly consisting of cellular basalt, to which, on the whole, he gives the preference, perhaps as not requiring the expensive employment of fuel for preparing it. "This hill," he says, "being but a short distance from the port of Leith, offers an inexhaustible abundance, at a small cost." We do not think this hint has ever been taken advantage of, as it might have been, especially since the great undertakings lately commenced on that hill have afforded an important opportunity. On the contrary, we have reason to believe, that the substance to which Mr Nicholson alludes, and which has been dug up, or blown, in large quantities, has been cast off as mere rubbish, for the filling up of vacancies. It may not be amiss to take notice here of a traditionary report, regarding an offer once made to the Magistrates of Edinburgh by some merchants from Holland, viz. to remove that hill free of expence. The common notion was, that they believed it to contain gold; probably they had remarked its abounding in a substance of greater real value.

Puzzolana.—A peculiar earth, found at Puteoli, in the bay of Baiæ, in Italy, from which circumstance it has often got the name of "powder of Puteoli," "Puteolian earth," and, corruptly, *puzzolana*, was used with great efficacy by the Romans as an addition to mortar, much in the way we have already described. As this earth is a sort of ferruginous clay, that seems to have been calcined by volcanic fire, there is every reason to believe, that similar minerals, subjected to the agency of heat, and then treated in a like way, will be found no less efficacious. All that is necessary is, that after burning, and in some cases this may be dispensed with, the substance be pounded down to a coarse powder, and then beaten up with lime, either with or without sand, in the manner already mentioned. This compound quickly sets under water, and acquires a degree of strength not inferior to that of many stones. Forge scales, brick and tile powder, coal-cinders, and a great variety of other substances, may be substituted for puzzolana, with perhaps equal benefit. The mortar-mill, a machine contrived by Mr Supple, facilitates the reduction of such substances. In some cases, where the utmost durability is needed, a certain quantity of bullocks blood, skimmed milk, or other glutinous fluid, is added to the water.

Glue,—is a substance of a viscid nature, prepared from the skins of animals by a particular process, and is used as a cement for wood chiefly.

The substances denominated *solder* and *putty*, belong to plumbery and glazing.

Sect. III. *Ornamental Materials.*

With regard to ornamental materials, most of the substances enumerated might here be reconsidered, as, in fact, almost every thing on which human ingenuity can be exercised, is capable of conducing to pleasing effect. But what we now allude to under this title, are those substances, which, whether essentially useful or not in the construction of buildings, are more commonly valued on account of their use as decorations. There are many substances of this kind, such as the *pigments*, or colouring matters; *stucco;* those used in mosaic work; certain *metallic* bodies applied to the locks and handles of doors; *paper* for covering the walls; *marble* for statues, slabs, and chimney-pieces. It is enough to have merely mentioned them here; and the reader will at once perceive, that the plan of this publication allots more suitable occasions for further notice.

Chap. II. Of the Strength of Materials.

Some materials are stronger than others, that is, bear greater force, or resist it more effectually, though perhaps of the same shape and size, and placed in like circumstances. The cases in which such comparisons have been made are so numerous, that one might imagine we ought, in this age of the world, to have been put into possession of an immense mass of information, highly valuable to the practitioner, and sufficient for the basis of an accurate science. But we shall err egregiously if we take the opportunity of acquiring information on any subject as the measure of the quantity acquired. We may lament, but we can be at no loss to account for the fact, that it is only of late years this subject has received the slightest elucidation in any of the elementary books which are the professed guides of our operative men. It is to the carpenter that it is chiefly interesting; and, fortunately for him, most of the experiments and observations have been made on the materials of his art. We shall state the most important results, premising some general remarks.

The heart of most, perhaps of all trees, is weaker than the outer parts, with the exception of that portion which is next to the bark, usually called the white or blea. The wood that is in the middle of the trunk is stronger than that at the origin of the branches, or at the root; and that of the branches themselves is weaker than that of the trunk. The wood that is on the south side of trees, (those of Europe at least,) is stronger than that of the north side. The heart of a tree is always nearer to the north side, which may account for this peculiarity. Timber is most tenacious whilst green, and loses of its strength in drying. From these remarks, it is evident, that different slips of the same timber may differ considerably in strength, and hence a vast number of experiments becomes necessary to afford even a few elementary propositions.

The strength of beams, as of all other materials used in building, depends on the cohesive and repulsive forces of the particles composing them, and these forces are variously called into action, according to the nature of the strain. Thus in the case of tension, that is, when a body is stretched, the form is retained by cohesion; in the case of compression, it is the repulsive force that is first engaged in resistance, though the cohesive force afterwards operates in preventing the particles or fibres of the body from sliding sideways on one another; whilst, in the third strain, called transverse, both these forces seem to be exerted at the same time, only in different parts of the body. We proceed to consider these strains more particularly.

Sect. I. *Of Transverse Strains.*

The strength of beams against transverse strains has been estimated by the weights which they can bear, or which are necessary to break them when they are fixed at one end, or at both ends. The most general theorem on the subject, for which we are indebted to Galileo, though in some degree hypothetical, is a very useful approximation to the truth. It may be thus stated:

The weight required to break a beam, having one of its ends firmly fixed in a wall, is proportional to the strength of its fibres, multiplied into the area of its section, and into the distance of the centre of gravity of this section from the point round which the beam turns in breaking, divided by its length. The weight is supposed to be applied to the free end of the beam; and the strength of the fibres is estimated laterally. It is nearly proportional to the specific gravity of a given bulk of the timber.

The strength of a beam having a rectangular section, all other things remaining the same, is very nearly as the square of the depth multiplied into the breadth. This is the result of some of Buffon's experiments. The real strength is rather less than this proposition makes it, and the more so the longer the beam is. But the exact amount of the decrease has not been hitherto ascertained, and probably will not, till the nature of the influence which the length of timber has on its strength be fully understood. Dr Robison, late professor of Natural Philosophy in the University of Edinburgh, proposed something like a solution of this question, but was candid enough to admit, that it did not merit implicit credit. According to him, a beam of quadruple length, instead of having one-fourth of the strength, as the rule states, has only about one-sixth part.

The strength of beams having the same length and breadth, being as the square of their depths, it follows, that the strongest beam that can be cut out of a given cylindrical tree, is that in which the breadth is to the depth as one to the square root of two; hence the strongest beam is not that which has the greatest quantity of timber, as will be seen when we mention a problem belonging to this subject.

The strongest form of a beam, however, of given length and weight, differs in different circumstances. In general, it ought to be thickest at the part most firmly fixed. Even the position in which it is placed, with respect to its own form, has an important effect on its strength. This is remarkable in the case of a beam having a triangular section. Its strength, for example, is no less than twice as great when one of its faces is uppermost, as when it is reversed. Similar to this is the very remarkable difference observed between the strengths of cylindrical beams and tubes, having the same quantity of matter. The latter, it is well known, are much stronger. Nay, there is still a more singular case, which it may be right to mention, though likely to stagger the faith of most readers. A tube of metal is said to support a greater transverse strain, than a solid cylinder having the same diameter; or a solid cylinder is strengthened against this strain, by being bored in the direction of its axis, and having a considerable portion of its substance removed. Mr Playfair has given a probable explanation of this paradoxical phenomenon, in his Outlines of Natural Philosophy.

The force necessary to break a beam transversely, is, very probably, to its force of cohesion, as the depth to from six to nine times the length; but cannot be in a greater ratio than as the depth to twice the length.

A beam supported at both ends, and having the same section throughout its length, is weakest in the middle; but it will bear there twice as much as either half firmly fixed would bear at the other end, or as it is able to bear when supported only at one end. This will be readily understood, by supposing it to be inverted, and to rest on a fulcrum in the middle; for the fulcrum will bear the sum of the equal weights at the ends, and the beam will bear a weight on its middle equal to its pressure on the fulcrum. If each end of the beam be firmly fixed, instead of being merely supported, its strength will be doubled, the circumstance of the ends being prevented from rising, adding a force capable of supporting the whole of the weight which the beam could originally support.

The weight which a beam, firmly fixed at one end, and projecting with a certain inclination to the horizon, will sustain, is greater than what it will support if projecting without any inclination, that is, if horizontal, in the ratio of the square of the radius to the square of the cosine of the angle of inclination. For the resistance of the beam is increased by the centre of gravity of the section being removed farther from the fulcrum; and the momentum of the weight again is lessened in the oblique position of the beam, by its perpendicular distance from the fulcrum being diminished; now these being each in the inverse proportion of the cosine of the angle of incli-

Materials.

nation, their combined effect is in the proportion of its square. Hence the great advantage of making the strain on timber as oblique as possible.

As the strength of beams decreases at least in the proportion of the square of the length, and the weight increases as the cube, it is evident that there is a limit, which, if a beam of a given shape, and of given materials were to reach, it could only bear its own weight. This, therefore, often requires to be considered. The usual way is to suppose the weight of the beam to be an addition to its load collected in its centre of gravity, and to allow for it accordingly. The length of time to which beams are subjected to a transverse strain, requires also to be considered. When a beam, therefore, has to sustain its own weight, as it does when placed parallel to the horizon, and is to be left long in this state, we ought not to put above a third or a fourth part of the additional weight on it that it is at first able to sustain.

Two thirds of the weight that is sufficient to break a beam when first laid on it, will sensibly impair its strength, and at the distance of some time, perhaps two or three months, will cause it to give way. One half of the weight produces a certain degree of curvature, which, however, will remain stationary for any length of time. One third of the weight will scarcely produce any permanent effect on the beam, which will recover its shape perfectly after having been so loaded for many months. One fourth part of the weight may be borne for ever, without producing the slightest set.

We subjoin to this part of the subject the following problem, which is of continual use in the practice of carpentry.

Prob. To cut the strongest possible beam out of a tree, the section of which is a given circle.

Let A E B F, Fig. 1. Plate 11. be the given section. Draw the diameter AB, divide it into three equal parts, viz. at d and e. From d or e draw a line perpendicular to the diameter, and cutting the circumference, as the line e E. Draw A E and E B. Complete the right-line figure A E B F, by making A F parallel to E B and B F to A E, both of them cutting the circle at F. This will give the section of the strongest beam that it is possible to cut out of the tree; for the square of the depth A E or B F multiplied by the breadth E B or F A is the greatest that can be produced, as might be demonstrated mathematically. Now, as the greatest rectangle that can be inscribed in a circle is a square, and as the section A E B F is not a square, it is evident that the strongest beam does not contain the most timber. To this we add an important result from some experiments of M. Buffon, founded on the fibrous or plated texture of timber, as made up of annual circular additions, the cohesion of which with each other is much less than that which exists between their own fibres. Let Fig. 2. Plate 11. represent the section of a tree, from which two quarterings as they are called are to be cut. Let A D and a d be the depths, D C and d c the breadths. The quartering A B C D will be stronger than a b c d, in the proportion where oak is employed, of 8 to 7. This, in certain cases, would be of material consequence, and will of course affect the results of experiments not instituted with attention to the fact. It seems to be on the same principle, that a number of planks set edgeways will be stronger than if laid one above another.

Materials.

Sect. II. *Of Tension.*

We have now to speak of that strain by which timber is drawn asunder, and which is intimately connected with its absolute strength, or the cohesion of its fibres.

Few experiments have been made on this subject that lead to practical purposes. Those of Muschenbroak, for example, were performed on small slips of timber, and, even admitting their accuracy, cannot with much propriety be held as authority for the case of large beams. It is desirable to prove the application by some on a greater scale; but this, from the difficulty and expense attendant on it, will not probably be soon executed. The fundamental principles in this particular case may be briefly stated.

The cohesion, or absolute strength of a fibre, is that force by which every part of it is held together, and is equal to the force which is required to pull it asunder. Supposing the texture of the body, therefore, to be uniform, and that consequently every particle or fibre has the same cohesion, it is evident that the whole cohesion must be proportional to the number of the fibres. The absolute strength or cohesion, therefore, in any part of a body, and the force which is requisite to tear it asunder in that part, are proportional to the section of the area, perpendicular to the direction of the extending force. It follows, that all bodies of the same texture, and presenting the same area of section thus taken, are equally strong in every part, and will therefore break alike in every part. And on the other hand, bodies having unequal sections, will break where the section is the least. The length of the bodies is immaterial in this case, and hence a long rope, or other cylindrical body, is neither weaker (as is commonly imagined,) nor stronger than a short one, in all other respects alike. But here also it may be noticed, a body may be so long as to break by its own weight. When hanging perpendicularly, it does so towards the upper end, although equally strong, the strain on that part being, in this case, equal to the weight of the whole that is below it: and hence we say, that the power of any part to resist the strain thus applied to it, is inversely as the quantity below it. In the case of the body being stretched horizontally, the strain arising from its own weight, as we have already seen, bears a sensible proportion to its entire strength; it must then be taken into account where an extending force is also at work. A flexible body, as a rope or chain, whatever be its strength, may therefore be extended so far, that is, be so long, that its own weight will break it; and hence the absurdity of a proposal that has sometimes been made, to construct a bridge of chains over a wide space.

Two-thirds of the weights requisite to tear bodies asunder will sensibly impair their strength, if long attached to them; and one-half is the utmost that can be perpetually attached to them without risk of injury. Those bodies which have the straightest fibres are best adapted for sustaining tension.

Sect. III. *Of Compression.*

We have now to consider a case apparently the opposite of the preceding, that of compression, one of still greater difficulty, and in which, notwithstanding its extreme importance, less has been ascertained in the way of scientific principle.

At first sight it appears difficult to conceive how the compression of a perfectly straight piece of timber should have the effect of breaking it. The tendency of the force applied at the extremes, seems rather to favour the cohesion of the parts of the body, and might be expected, therefore, to increase, not to lessen its strength. On the supposition, indeed, of any obliquity in the direction of this force, it is easy to understand how certain parts may slip on each other, and, consequently, the beam be fractured. Nor is it difficult to perceive how a force, acting on the beam in a direction perpendicular to that in which the compressing force acts, should produce a certain degree of curvature, and hence allow the approach, if we may use the expression, of the compressed extremes, that is, contribute to the fracture. But on the supposition that the particles of a column are perfectly hard, and in contact, and, at the same time, that the fibres are all arranged in the direction of the pressure, it seems impossible to conceive how they can be disunited by it. But this supposition is a very arbitrary one. Whether there are such bodies, may well be doubted; or whether, if there were, they would be totally indestructible and inseparable by compression, it might be difficult, if not impossible, to determine. We must content ourselves with the consideration of such as are commonly met with, and are usually employed in building.

Timber, beyond all doubt, does not answer these conditions. Neither are its particles perfectly hard, nor are its fibres uniformly in the direction of a compressing force. On both accounts, therefore, it may be expected to yield, and of this we have infallible proofs. It is very evident that the effect of the pressure will be to increase the curvature of the fibres, and, therefore, that, at last, by augmenting the weight, the fibres will give way, and the beam be broken.

The peculiar nature of the wood, it is easily to be understood from what has been said, will materially influence the effect now stated to take place. A very soft wood is easily compressed. This may happen either from the particles being at considerable distances from one another, or because their fibres are very much incurvated. But some hard timbers, owing, it is probable, to this last circumstance, are less capable of resisting compression than others which are of a softer nature. Oak, for example, though it will endure tension better than fir, does not carry so great a weight. The proportion has been rated as high as two to one in favour of the latter. But this, perhaps, is too high. The artist, however, will attend to the difference, and accordingly employ these two species of wood for different purposes. The disproportion between the powers of some bodies, in this respect, is immense. Glass, for instance, is said to be able to bear a hundred times the weight that oak will do, though it will not suspend above four or five times as much.

It would be convenient to know the various powers of different substances, as to this particular. Judicious experiments are required to determine them; few have hitherto been instituted on which we can rely. A very hard freestone, whose section was a square foot, was found to bear 664,000 pounds with perfect safety. Its highest strength was much greater, 871,000 pounds. Some inferior pieces did not bear more than 460,000. A soft freestone, of similar dimensions, bore from 187,000 to 311,000 pounds. The safe load for it was averaged at 249,000 pounds. This is inferior to the strength of good brick, which is said to carry 320,000. Chalk, a very soft substance, carries only 9000 pounds. Sound oak is supposed to require above 60 pounds on every square line to crush it.

The proportion between the strength of a body thus tried, and the area of the section which it presents, has not been ascertained. The theory of Euler, that the strength was as the biquadratic power of the diameters, is at variance with experiments. It is not proportional to the area, as has often been imagined, nor to any power or function of the area. In certain cases, there appears to exist a relation between the forces opposed to tension and compression, and not in others. In short, the whole subject requires elucidation.

When a beam or column is overloaded, it is observed to increase in diameter; it then cracks or shivers longitudinally, and at last gives way. The process is called *crippling*. It may occur in a variety of situations, as the compressing force is perpendicular to the horizon, parallel with it, or inclined at any angle. The length of the column has no effect on its strength, unless a transverse strain takes place; and this the carpenter guards against, by the use of what are called transverse bridles. The employment of hoops, metallic rings, ropes, &c. materially increases the strength of beams exposed to compressing force.

Sect. IV. *Of the Twist.*

There is still another kind of strain to which materials are sometimes subjected. It is the case of twist. This occurs principally in pieces of machinery, and especially in the axles employed to communicate motion. To the house-carpenter, this is comparatively unimportant, as he rarely has to expose his materials to such a trial. We shall merely remark respecting it, that the strength by which an axle or beam opposes twisting, or being wrenched, is generally proportioned to the cube of its diameter, and that the internal parts do not resist so powerfully as the external. Hollow tubes, therefore, have a greater superiority over solid cylinders, in resisting this kind of strain, than a transverse one. Many cases occur, in which both advantages may be obtained, and prove of immense consequence. Accordingly, engineers are now much in the practice of using hollow axles of cast iron, wherever the size will allow of the preference.

PART II. OF THE PRINCIPLES OF CONSTRUCTION.

The chief object of architecture, considered in a philosophical point of view, is to resist the causes of motion, or withstand the force of gravitation. The means of resistance are found in the various kinds of strength of the materials which it employs; and, generally speaking, there are three ways in which the object is accomplished, viz. support, suspension, and equilibrium. Every building exhibits at least one of these modes of effecting stability, and in many buildings we have examples of all the three combined. It is unnecessary, after what has been said in the preceding part, to occupy much room in treating of the two former, at least in a systematic manner. The last demands more of our attention, both because of its extreme importance, and as not having been so much as hinted at previously. There are some general laws, however, of an abstract nature, common to the whole, which we must first elucidate.

We shall treat, therefore, 1. Of the general principles of construction, including the third mode of resisting gravity, now alluded to; and, 2. Of some particular principles exemplified in certain productions of the art.

Chap. I. General Principles of Construction.

The chief proposition in the mechanical adjustment of materials, respects the composition and resolution of forces. It is of continual application in practice, and, together with the principles of the arch, which are afterwards to be considered, may be said to constitute the theoretical basis of architectural science. We shall study the convenience of general readers in our mode of explaining it.

Sect. I. *Composition and Resolution of Forces.*

If a body at A, Fig. 3. Plate 11. be acted upon at the same time by two forces; one in the direction of A B, and the other in that of A D, the intensities of which are proportional to these two lines, it will be affected in the same manner as if it were acted on by one force in the direction of A C, having an intensity proportional to that line, which is the diagonal of the parallelogram A B C D. If the forces acted in the directions of the lines A F and A G, or A K and AL, or AM and AN, and were respectively proportional to these lines, a similar effect would be produced, and the body would be operated on just as if only one force acted on it in the same direction A C, which is the diagonal of the three additional parallelograms represented by the dotted lines. A variety of parallelograms might be constructed, of which A C would be the diagonal; and there are as many combinations of forces, as may be conceived, which, acting on the body at A, would produce a similar effect. The slightest inspection of the figure will convince the reader, that as the directions of the forces approach nearer to each other, or are least distant from the diagonal, these forces most coalesce, or least oppose each other; and, on the contrary, that as the directions recede from each other, their opposing effect is the greater. If the directions, therefore, be the same, that is, both in the direction A C, the full effect produced is the simple addition of the effects of the two forces, that is, it is proportional to the line A C. On the other hand, if the directions be contrary, the effect will be that of the difference of the forces. In the former case, if the forces be equal, the body will be moved in the direction of the diagonal with a force which is double of that by which it would have been moved by one of them acting alone. In the latter case, if the forces be equal, the body will remain at rest.

The reader may amuse himself with observing the effects of combined forces on a moveable body, such as a ball to which two strings are attached. If the ball be laid on a horizontal surface, a table, for instance, it may be made to trace the same line by drawing the strings with both hands, at a variety of angles; and by a little practice he can vary also the intensity of either or both of the forces, so as to represent all that we have now mentioned. But he can more correctly perform these experiments by the help of small pulleys and weights, as is represented in fig. 4. This is easily explained.

The pulleys P and R, are fixed on a vertical surface, as a wall, or perpendicular board, so as to allow the easy motion of the cords, A P q, A R s, to which the weights q and s are suspended. At A is attached another cord, A T v, to which the weight v is suspended. These weights, acting separately, would draw the point A, in the directions A P, A R, A T. But if they all act at once, provided the weights q s, together, are greater than the weight v, we shall find that the point A will settle in a certain position, and if drawn out of it will always return to it. We say, that in this case, A is in a state of equilibrium, and that the weight v is opposed to the joint action of the weights q and s, and is equivalent to it. Now, an equal weight, x, attached to the cord A W x, going over the pulley W, exactly balances the weight v, in the contrary direction; we say, therefore, that the point A, is affected by the joint action of the weights, q and s, in the same way as if it were drawn upwards by the single weight x. If, therefore, we take A C as the measure of the force of x, or of the equal and opposed force of v, and A D and A B as the measures of the forces of q and s, having the same proportions to A C as q and s have to v or to x; and if we draw the lines C D and C B, we shall find that C D is equal and parallel to A B, and C B to A D, and that the line A C is the diagonal of the parallelogram A B C D. This will always be the case whatever weights we employ, provided *that* one which is in the situation of v be less than the sum of the other two at q and s, and that no one exceed the sum of the other two. We can resolve a motion or pressure, therefore, into two equivalent ones, and combine two forces together, so as to produce a motion, or pressure, in one direction only. It is easy to invert the arrangement now described, and to conceive solid materials used in place of cords. Fig. 5. represents such an adjustment. The beam A T, loaded with the weight v, rests on the ends of two beams A P, A R, whose farther extremities press on the two masses q and s. The pressure on these two beams is evidently in the direction of their lengths. In order to ascertain the amount which either sustains, we take A C to measure the pressure of the beam A T, thus loaded, representing the number of pounds, for example, on a scale of equal parts. Then we draw C D parallel to AB, and C B to A D, completing the parallelogram A B C D. The beam A R sustains a pressure, represented by A B, and the beam A P a pressure, represented by A D, both measured on the same scale. If, in place of the beam A T, there be a weight hung on at A, as x, at the end of the cord A W, whose force is also measured by A C, the pressure on the two beams A P and A R, will remain the same. Nor will it make any difference, if, in place of this rope, a beam be supposed in the same situation, and used in such a manner as that its downward pressure be still represented by A C. In all these cases, it is obvious, that the strain produced is that of compression, and that the measure of it is the same.

But if we vary the angle of inclination of the beams to each other, we vary also the proportion of their pressures. This will be perceived from the inspection of Fig. 6. which may be fully comprehended without any verbal explanation. It will be seen from this figure, similarly to what was mentioned when speaking of Fig. 3. that as the directions of the forces approach there is less expence of power, or, to use a common phrase, the purchase is the greater; and that, on the contrary, the strain on the materials is augmented as their inclination to each other is increased.

But compression, we have seen, is not the only strain to which beams are subjected. They are liable to be drawn asunder. This will be seen in Fig. 7. a case which is of frequent occurrence. The beam A T is not compressed, but suffering tension, and might have its place supplied by a cord or rope, which certainly would not answer if the former sort of strain were that which it had to endure. In this case A T is stretched by a force, represented by A D, and A P, on the other hand, is compressed by a force represented by A B, the line A C being the diagonal of the parallelogram A B C D, and representing the full amount of the force acting at W. A material difference in the strain will be produced by altering the position of AT. Let it be placed in the direction A E, whilst A P remains as before. The pressure on this last will now be represented by A P, and the force of tension on A E by A R, both very much increased. The same thing would happen by changing the position of A P, whilst that of A T remained the same. This will be seen in Fig. 8. In this case, A T is stretched by a force represented by A D, and A P is compressed by a force represented by A B.

Sometimes both the beams sustaining the strain are in a state of tension. This can be easily shewn as in Fig. 9. Here both A P and A E, attached together at A, are drawn downwards by a weight, whose force is represented by A C; it is very obvious that two ropes might be substituted in their place. On the other hand, the force stretching them might itself be a beam suffering tension, in which case all the three beams are on the stretch. This, though unusual, is occasionally met with.

The reader may easily construct a great variety of such figures as we have now shewn; it will be a good exercise for him, as he will thereby learn to discriminate between the two states of compression and tension; and it may be proper to furnish him with a simple rule, the employment of which will prevent his confounding one with the other in any combination of materials. This we shall give in the words of Professor Robison, to whose Treatise on Carpentry, in the First Supplement to the Encyclopædia Britannica, we are indebted for much useful information on the subject.

Observe the direction in which the piece acts from which the strain proceeds. "Draw a line in that direction from the point on which the strain is exerted; and let its length (measured on some scale of equal parts) express the magnitude of this action in pounds, hundreds, or tons. From its *remote* extremity draw lines parallel to the pieces on which the strain is exerted. The line parallel to one piece will necessarily cut the other, or its direction produced. If it cut the piece itself, that piece is compressed by the strain, and it is performing the office of a strut or brace; if it cuts its direction produced, the piece is stretched, and it is a tie." We have given sufficient examples of both for all the purposes we have in view. The following remarks from the same work will be found of utility in studying the principles of structures.

"If the straining piece is within the angle formed by the pieces which are strained, the strains which they sustain are of the opposite kind to that which it exerts. If it be pushing, they are drawing; but if it be within the angles formed by their directions produced, the strains which they sustain are of the same kind. All the three are either drawing or pressing. If the straining piece lie within the angle formed by one piece and the produced direction of the other, its own strain, whether compression or extension, is of the same kind with that of the most remote of the other two, and opposite to that of the nearest."

Thus far of the directions of the strain. As to their measures, it is enough to remark, that they can always be obtained by drawing the parallelogram in the manner we have done, the sides representing it being, of course, measured on the same scale of equal parts as the diagonal. It is necessary now to take notice of the strains as propagated to the points on which the pieces are supported. The pieces, it is evident, are instrumental in communicating the strains to which they are subjected; and it is important to learn how the same measures of the forces will apply to the supports. All that we need to offer on the subject are some general considerations.

Bodies act on each other in directions perpendicular to their touching surfaces. The support, therefore, which a prop gives to a beam is in this direction. Obviously, then, we may, by the same process which we have hitherto adopted, measure its force, and resolve it into two constituent forces. It is unnecessary to go over the steps, as the attentive consideration of what has been said on the subject of the composition and resolution of forces, will enable the reader to make the proper application to the present case. He will not fail to remember also, that the general rules for the discrimination of the strain, whether that of compression or of tension, equally hold true as in the former case. Examples of the force of tension being exerted on the prop are of common occurrence, even where solid materials only are used. This generally happens when the forces act very obliquely on the two ends of a beam, the cohesion of which only operates in resisting the extension. But the beam itself must be supported, and hence we are led to refer the whole frame to something else, of which it is a part. This frame, in fact, becomes an element in a more extensive piece of mechanism, to which it communicates pressure, much in the manner of a lever. The elucidation of this remark is given, in a very beautiful and satisfactory way, in the treatise above-mentioned, to which, and to some other treatises there referred to, we must direct the scientific reader.

Sect. II. *The Construction of Arches.*

By the term arch is meant a building in the form of the segment of a circle, or other curve, used in bridges and other works where great weight is to be sustained. It is an assemblage of materials in the form of truncated wedges, so arranged as to give support to each other when under pressure, and, at the same time, maintain a communication between distant points, without filling up the whole of the intermediate space below. These wedges, which are generally of stone, are called the *voussoirs*, the central one receiving the name of *key-stone*, and the surfaces which separate the voussoirs from each other being denominated the *joints*. Besides these terms, there are others very commonly in use, when speaking of arches, which it is necessary to define. The interior curve of the arch is called the *intrados*, and the outward one the *extrados*. The points on which the extremities of the arch rest, and which are usually masses of masonry, are called *abutments*. That part of the abutment from which the arch springs is termed the *impost*, the beginning of the arch receiving the name of the *spring*. The middle of the arch is called the *crown*, and those parts which are between the spring and the crown are the *haunches*. The arch is said to be an *arch of equilibration*, when the parts of which it consists are so adjusted as to be *in equilibrio*, or to balance one another by their weight only; and this is conceived to be the most advantageous principle on which arches can be constructed. But equilibrium of its parts is not alone sufficient to secure the strength of an arch, the powers of cohesion and lateral adhesion being also employed. The curve of the intrados being given, it is evident, from what has been said, that the weight of the voussoirs is also determined; but here, it ought to be remarked, that as the stones cannot always be made in the proportion necessary for equilibrium, they are supposed to be extended upwards by courses of masonry, and, accordingly, the whole mass included between the planes of their joints, thus supposed to be produced as far as that masonry extends, is understood to constitute the weight of each voussoir. For more particular information respecting the construction of arches, we must refer to those authors who have expressly written on the subject, especially to Dr Hutton's *Principles of Bridges*, and Mr Atwood's Treatise on the Construction, &c. of Arches. Mr Playfair has given the most important principles in his Outlines of Natural Philosophy.

The discovery of the nature and properties of the arch must ever rank among the highest benefits which accident or reasoning has conferred on mankind. To the former we do not hesitate to assign it; and, farther, we think that the theoretical speculations which have been founded on it in modern times, have contributed little real improvement to the maxims which previously existed. This assertion, it is probable, will be borne out by the additional remarks we have to make on the subject. And hence we shall not seem to have neglected the reader's instruction, when we scrupulously avoid the intricacies in which some profound inquirers have continued to involve it. Without calling in question the validity of her claims, we doubt the necessity or utility of the interference of mathematical science, to the full amount of her attainments, in matters which had certainly prospered previously to her exalted pretensions; though we are well aware of the satisfaction that arises in the minds of her votaries, on the discovery of coincidences between her precepts and the successful exertions of untutored genius. But it is too much, to insist that such cases should be ascribed to her inspiration. There is no evidence for such an opinion, and we are left accordingly to imagine, as we best can, how the deductions of a very abstract philosophy, fostered, if not produced in modern times, were anticipated and acted on by the artists of an earlier age. The theoretical principles of arches, in fact, seem not to have engaged the attention of mathematicians till far on in the eighteenth century, while the use of them, even on a large scale, is at least as old as the brighter days of the Roman empire.

Casual arrangement of materials might suggest the rude notion of an arch to the primitive builder. In erecting his wooden hut, it would almost necessarily happen that some of the trees or beams which he employed should assume the position represented in Fig. 10. A. Plate 11. by falling against each other. Or such a position would be certainly given them in order to afford the means of covering his dwelling from the weather. It is obvious, that a beam, having a tendency to fall to a side, in consequence of its centre of gravity being out of the line which passes through its length to the ground, would be prevented from yielding to it by another beam placed in a similar situation, but with an opposite inclination. The two beams thus counteracting each other's tendency to fall, would even acquire a new power to resist a thrust in the plane of their opposition; and this position, accordingly, might be had recourse to, in certain circumstances where a lateral pressure was to be exerted, which could not at all, or at least so securely, be encountered by one beam standing upright. But

Construction

these beams meeting only in a single point, would be easily caused to slip on each other by an oblique pressure, when they would, of course, fall. It was a simple improvement to increase their connection by plaining their heads, so that they pressed together through a larger space. Even the intervention of a third body, between these ends, which, by its form, accommodated itself to both, might be suggested by this slight alteration. It is not unlikely, also, that both the builders in wood and stone might sometimes meet with such an arrangement as is shewn in Fig. 11. B. Plate 10. in the accidental disturbances of their materials. If so, it could not fail to give rise to some profitable reflections. The upper piece, it would be seen, could not fall down unless one or both of the side pieces gave way, and these again, provided their lower ends were prevented from slipping, received a degree of counteracting pressure from it, much in the manner they did when simply leaning against each other. It was no great stretch of reason, although no new accident aided in the discovery, to conceive that two pieces pressing against each other, as in the first case, might be substituted in the place of this single piece, as in the second case. In this last arrangement it would not be forgotten to give a firmer hold to the pieces, by making their place of junction as equal as possible; nor would it seem unnecessary to seek for additional firmness by adjusting their abutting extremities to the ends of the lower pieces. We have now obtained the construction represented in C, and this, in fact, comprises the principles of the arch. If to this a keystone be added, as in the second case, we obtain the arrangement given in D.

So far, the reader will remark, no dependence is put on any cement which might be used to connect these materials. Their stability is altogether the consequence of the proper balance given to them, by which they support one another. We have now both pointed and circular arches; and if we multiply the pieces of which they consist, giving them proper length of joints for resting on each other, and sufficiently supporting the lower part of the sides, so that they may not slip outwards, it is reasonable to think there is hardly any space too wide to be arched over.

We have ample proof of the sufficiency of these simple principles in Gothic buildings, and still greater in the immense bridges which very common workmen have executed. Of some of these examples we shall have occasion to speak presently. All this is not enough for the zealous mathematician, who must introduce his diagrams and analytical investigations, to the utter perplexity of common sense, and, in truth, if followed faithfully, the utter ruin of all good practice.

Dr Hooke, certainly an able man, may be said to have led the way in the introduction of that useless parade to which we now allude. He pointed out clearly enough the principle on which the equilibration of arches might be effected; but, in fact, whatever was good in his theory had been anticipated many centuries before his time, and, on the other hand, some things in it are at variance with the better dictates of experience. We hold it quite useless, then, to occupy much space or time in discussing the merits of the Catenarian curve, as it has been called, or the theoretical deductions which have been made from it. We shall be vastly better employed in attending to the operations of the architect, whilst accomplishing this most important part of his profession, and providing against the evils which reason and experience teach him to apprehend.

Arches are constructed both for ornament and for use. Those of the former kind, having little or no weight to sustain, may be of such curves as are held most pleasing to the eye. Those of the latter kind may seem to require greater caution, as well in the selection of the curve to be given them, as in the mode of finishing. In point of fact, however, arches intended for use have been executed of curves which mere theory would have totally proscribed. Circular arches, for example, have long been common, and are abundantly trust-worthy, though a celebrated mathematical theory asserts their absolute incompetency, unless, which is absurd, and amounts, of course, to an interdiction, they be loaded with an infinite weight where they spring from the horizontal line, or at least that the load, for a considerable distance upwards from the spring, be many times greater than ever will or can be accumulated. These arches, too, it may be observed, when they give way, do so at places very different from those which this theory would point out. And, on the other hand, there is good reason for supposing, that the curve which this theory recommends, is, in fact, almost the only one that would be found defective for common purposes. In short, this theory has made assumptions which seldom or ever exist, and has neglected circumstances of universal occurrence. Architects of the highest repute, therefore, who themselves were acquainted sufficiently with mathematical science to value its injunctions, have abandoned this theory, and betaken themselves to much more obvious principles for the determination of their practice. This will be seen when we describe some of the great monuments of their skill in this branch of the art.

Chap. II. Particular Principles of Construction.

Both carpentry and masonry, the chief practical branches of architecture, afford examples of those general principles. It will be best for our purpose to adduce those only in which there is also some particular display of science. We propose, then, to consider the nature of Roofs, Domes, Centres, and Bridges, on each of which we shall make some general remarks, and afterwards add a few details by way of practical illustration.

Sect. I. *Of Roofs.*

By a roof is understood the covering of a house, serving to defend the interior and its inhabitants from the inclemencies of the weather. It is, therefore, a very essential part of a building; and its due construction, besides, requires a great degree of skill.

The simplest form, next to a mere flat cover, of which we need not speak, consists of two beams, or

Construction

rafters, as they are called, as A B and B C meeting in the ridge B, and resting on the walls E and F; Fig. 11. Pl. 11. A number of such frames, laid parallel to each other, at certain distances, and connected by means of cross or horizontal pieces, on which are fixed the slates or tiling, &c. will answer the purpose of a roof of no great dimensions, and where there is not much weight to be sustained. Even in this simple construction there is room for the exercise of judgment, in the determination of the pitch or height of the roof, and the size or strength of the timber to be employed, besides the consideration of the manner in which the rafters are to be bound together. The best form will be that in which the relative strength of the rafters, and their mutual support, give the greatest product. But this cannot be determined with accuracy on mathematical principles, without taking into account the curvature which the supported rafter acquires, by the transverse pressure of its superincumbent load. This might give rise to rather intricate calculation, and is, of course, altogether neglected by the common artist. Economy usually induces him to prefer a low pitch; and he is generally guided, as to form, by a regard to the appearance of equality in the sides of the roof, or some peculiar circumstances in individual cases.

The chief thing to be regarded here is the thrust which such a roof makes against the walls of the building, tending to push them outwards. This is the most hazardous strain to which they can be exposed, as ordinary walls generally require, from their thinness, to be tied together to prevent separation; and this, accordingly, is often done by means of cross-walls, joists, and roofs. To remedy this pernicious defect in the roof now described, it is usual to introduce another beam connecting A and C together, which, from its office, is called a *tie*, or *tie-beam*. This is shewn in Fig. 12. With respect to the other members of the roof, this can be considered in no other light than as a rope tying the ends of the rafters, so that they shall not press the walls outwards. As, however, it acts with its whole absolute force, and is generally made of larger dimensions than is necessary, in order to admit of being firmly fastened to the ends of the rafters, it is often employed also for carrying the cielings of the apartments under it, and even for supporting a flooring. If made of oak, the tie-beam may be safely subjected to a strain of three tons for every square inch of its section; if of fir, to that of two tons.

But when the tie-beam has a great span, or is much loaded, it may give way, and then the whole thrust of the rafters would be against the walls, as already mentioned. It sometimes yields considerably, or *swags*, as the workmen call it. It therefore needs support, which is afforded by what is known under the name of a *king-post*. This is a very useful contrivance, and admirably answers the end, as may be easily understood by Fig. 13, in which B D represents the king-post. The rafters, we have seen, have a tendency to spread out at the walls on which they rest. This is prevented by the tie-beam exerting a pressure, by which they tend to compress each other. Their weight, however, presses in a contrary direction; and the consequence of this is the stretching of the tie-beam. But if these be in equilibrio, the whole frame, A B C, will retain its shape, and therefore B will become a fixed point, on which the king-post may properly be suspended. The king-post is certainly a tie attaching the tie-beam to the ridge, and suffering tension just as the tie-beam itself does.

Construction

We have now supported our tie-beam; but still our rafters require something to prevent their being bent under the weight of covering laid on them. Any thing of the nature of a tie, is here out of the question; there is no point from which they could derive aid in the way of suspension. But the king-post presents us with assistance. We can raise up *struts*, or *braces*, as they are called, from the foot of it, in the direction of the rafters, to such places as seem most likely to bend inwards. This, of course, is about the middle, to which accordingly the upper ends of the braces are applied, their lower ends being firmly fixed or mortised into joggles, as the carpenters speak, on the foot of the king-post. This will be easily understood from Fig. 14. without farther remark.

These simple constructions are pretty generally applicable, and may be held as the elements from which all the more complicated roofs are produced. There is one piece, indeed, very often employed in comparatively simple roofs, and of course in others, which it is necessary to describe. This is called a *truss*, or *strutting-beam*. It is essential for roofs that have a flat on the top and two sloping sides; those that have a double slope called *kirb*, *curb*, or *mansard roofs*; and others, which, having a valley in the middle, are from their figure denominated M roofs.

Fig. 15. represents a flat-topped roof, of which B C is the truss-beam. It lies between the rafters A B and C D, much in the manner of the key-stone of an arch, and is evidently in a state of compression. The pressure which it occasions on the rafters is the same as if they were produced onwards to the point of meeting, as in the roofs already described, and a weight were laid on them equal to that of B C and its load. We may conceive the truss-beam, indeed, as supplying the place of that portion of the rafters which would be requisite to bring them into contact in the common manner; and if it be of dimensions sufficient to carry its own load, and withstand the compression of the rafters, it will be equally strong. The shape of this roof, however, is not so firm as that before described, at least without some addition in the way of ties or braces to prevent the change it is liable to undergo from unequal weights applied to its sides. The addition of side-posts, such as B E and C F, is a common expedient. The heads of these are secured between the rafters and the truss-beam, or strut, as it is often called, and their lower ends are connected with the tie-beam, which is thus suspended, much as it is by a king-post. This is a very useful construction, as it allows room for garrets. But it is not quite so strong as the former, at least without some increase of timber. The truss-beam is subjected to great compression, besides undergoing a transverse strain from its own load, and the tie-

beam, too, is liable to some degree of transverse strain, when one side of the frame is more pressed down than the other. Fig. 16. shews another construction for a flat-topped roof, certainly stronger, but not quite so convenient for garrets. Sometimes the truss-beam is included very advantageously within the rafters, preserving the common pent form. But in order to obtain the full benefit of it in such cases, what are called butting rafters must be placed under the principal ones, resting on joggles in the heads of the side-posts. An example of this is given in Fig. 17. in which also a king-post is represented as suspended from the ridge of the single rafters, and serving to steady the truss-beam. It exhibits, besides, a set of braces for the upper part of the single rafters, and another for the butting rafters. This frame, therefore, is intended for a wide space, where considerable security is required.

Such, then, are the principal pieces of which a roof-frame is composed, and such is the general principle contemplated in their adjustment. It can rarely happen that more pieces are necessary; if they are so, there is reason to think that some injurious cross strain will be produced. In general, the simpler the construction is, the greater is the security from such an occurrence, and the less the danger of error or imperfection in the workmanship. These pieces may be very variously combined, so as to answer different circumstances.

A case of pretty frequent occurrence, and some nicety, for a simple roof, ought to be noticed. It is where great elevation is wanted within for arched cielings or other peculiar purposes. The common tie-beam would prevent the attainment of this object. Two *hammer*-beams, therefore, or *stretchers*, as they are called, are substituted for it, as is shewn in Fig. 18. and these are connected together with the king-post, somewhat shortened, and the two rafters, by means of iron straps. This is not so strong as the frame in the common way; and as all roofs settle a little, this is apt, by making the points B and D to descend, to cause the rafters to spread out, and hence occasion an outward pressure on the walls. Such a roof, therefore, requires farther management in order to prevent mischief. It may be greatly aided by introducing something like a truss-beam between two rafters, the feet of which are supported lower down on the walls, as is represented in Fig. 19. These take off part of the weight, and lessen the thrust on the walls.

A curb roof, or Mansard roof, as it has been called after the inventor, is a still more ingenious contrivance, and may rank indeed amongst the chief productions of modern carpentry. It is formed by the application of four or more planes to each other, so that each two may have an external inclination, the ridge being the point of meeting of the two middle planes. It may be constructed for any given height and width, and with any number of rafters. On this account, and because the lower rafters may be made to spring at a very small angle from the walls, occasioning therefore little lateral pressure, this roof has important advantages over the common ones, where great space is required immediately below it. If the sides be properly balanced, or the rafters have a just proportion to each other, in which alone consists either the difficulty or the excellence of the structure, this roof admits of the upper part being a complete void to the very ridge, or forming a cylindric arch, in which respect it differs essentially from all those roofs which require tie-beams, king-posts, &c. in their construction. For the theoretical and practical principles of curb-roofing, we refer the student to Mr Nicholson's Architectural Dictionary. Figures 20. and 21. represent the outline of some of the usual forms which it takes.

We have still to notice another kind of roof, before we proceed to describe some remarkable examples. It is denominated a Norman roof, from the circumstance of its having been often used by the people of that name, after their establishment in the southern countries of Europe. Its structure is ingenious, is capable of great strength, has a pleasing appearance, requires only small pieces of timber, and, like the last-mentioned, exerts little lateral pressure on the walls. In this roof, represented in Fig. 22. all the rafters are butted on joggled king-posts, of which there are several, as A F, B G, &c. and there are braces, or ties, placed in the intervals. Such is the general principle, but there are several modifications to be met with, which, however, we do not think it necessary to particularize. We have noble examples of Norman roofs in the Parliament House at Edinburgh, the great hall in Tarnaway Castle, belonging to the Earl of Moray, in Scotland, and in Guildhall, London.

The following examples of roofs are chiefly taken from Nicholson's Carpenter's and Joiner's Assistant, Lond. 1810, which the artist, who desires to be particularly informed respecting the dimensions of the different pieces, will do well to consult. We shall content ourselves with general observations.

Plate 12. Fig. 1. is the old roof of St Paul's church, Covent Garden, as executed by *Inigo Jones*, which was consumed by fire in 1795. It is somewhat singular, the nature of the building requiring it to project over the walls, which it does to the extent of seven feet on each side. It could not rest therefore on the tie-beam, the ends of which were employed in the support of certain external ornaments, of what has been called the Tuscan order, to be afterwards spoken of. But the deficiency is artfully remedied, and that too with little timber. This was reckoned the highest roof of its width in London. Mr Nicholson points out some imperfections in this structure, which, however, we think it unnecessary to specify. We agree with him in giving the preference to the new roof, Fig. 2. as both simpler and stronger, though, to use his words, 'it must be observed, in favour of the modern improvements in carpentry, that a truss of the old roof contains about 273 solid feet of timber, whereas the new roof contains only about 198 feet in each truss." The whole length of the tie-beam in both roofs was 72 feet. Fig. 3. is the roof of Islington church, near London, built about the year 1752. Sundry and serious objections may be made to it, being complicated, occupying much timber, and subjecting the pieces from the form and positions given them to revolve at the angles. In place of it Mr Nicholson proposes, Fig 4. as much better suited to the

purpose, and evidently stronger, though taking less timber. We think the claim is just. Fig. 5. is the excellent roof of the chapel of the Royal Hospital at Greenwich, constructed by Mr Samuel Wyatt about the year 1785. It is flat on the top, having what is called a camber beam for supporting the platform. The king-post is of iron, and the joints are secured by iron straps. The structure, though simple enough, is far from being a common one. It is in such performances that the genius of an artist is to be seen. Fig. 6. the roof of Birmingham theatre, constructed by Mr George Saunders in 1794, has very great merit, being well adapted to the circumstances and required magnitude, whilst the construction is simple and employs little timber. The open space in the middle, it will instantly be understood, is used for the various work-rooms, &c. necessary in a theatre. Fig. 7. the roof of the present Drury Lane theatre, constructed by Mr Wyatt, which we have copied on a reduced scale from his account of that edifice, is an admirable combination of simplicity, strength, and conveniency. One of the most scientific, and certainly the largest roof we have ever heard of, is that of the riding school at St Petersburgh, said to be the production of a native of Scotland. We are indebted to Mr Charles Black, builder in Edinburgh, for a drawing of it, a reduced copy of which is given in Fig. 10.; and to Mr James Haldane, teacher of architectural drawing in the same city, for all the information respecting it that we have been able to procure. A short time before his death, Professor Robison employed this last gentleman to make a draught of it from the scroll and particulars communicated in a letter of a Russian nobleman. The professor, an excellent judge, conceived it a master-piece of carpentry, and no doubt intended to make it generally known through the medium of some literary publication. This, at least, as far as we know, was never done. The reader will scarcely hesitate in thinking, that we do a service to a useful art by the present notice. Whoever attentively considers the width of this roof, viz. 126 feet clear within the walls, (that of old Drury-Lane and Birmingham theatres being only 80,) the lowness of its pitch, the skilful adjustment of its various pieces to the nature of the offices which they perform, and its general indication of judicious design, with the production, at the same time, of very pleasing effect, must admit, we believe, that, both as a study and a model, it merits the very highest commendation. With this fine example, then, we conclude our account of roofs.

Sect. II. *Of Domes.*

The subject of domes is intimately connected with that of roofs, a dome being, in fact, an arched or vaulted roof. They vary in appearance according to the nature of the surface from which they arise, and the height to which they are carried, and obtain, consequently, different names. Thus they are circular, elliptical, or polygonal; and these two may be subdivided. When they arise higher than the radius of the base, domes are said to be *surmounted*; when they are of a less elevation they are called *diminished* or *surbased* domes. Such as have circular bases are termed *cupolas*. They generally present a convex surface outwardly and are concave within; sometimes though rarely in this country, they are made convex below and concave above; and it is certain, from the principles on which they are constructed, that they might be made with a convex surface inwardly and a concave one outwardly, and yet be equally if not more firm.

The construction of a dome evidently requires science. Most persons, it is presumed, will conceive it more difficult than it really is. There is considerable advantage, in fact, in some of the usual circumstances of domes. We see, accordingly, that common workmen, without any particular attention to scientific rules, succeed perfectly in building very lofty edifices of this kind, such as glass-houses and potters' kilns. It would be extremely difficult to raise a pent roof to half the height of some of them. In the case of a cone, then, at least, some facility seems to be afforded by the roundness of the horizontal section, and therefore we find that even very small materials will suffice for accomplishing the structure. The chief thing to be regarded in this case, is a provision against the bottom flying out, which we can have in an iron hoop or a stone bandage, &c. It is easy to understand, that if all the joints of this building be directed towards the axis, they will all have an equal tendency to slide inwards, and therefore, as no one can have a preference, that they will hold one another in equilibrio. The pieces, in short, are wedges, and operate as such. On the same principles, it follows, that a dome may be loaded immensely at top, with perfect safety, so long as the bottom course is prevented from bursting; nay, that such load may even have a good effect in guarding it from the injurious operation of an irregular pressure on its sides. We have a good example of what a dome may bear, in this way, in the case of St Paul's cathedral, London, the production of the celebrated Sir Christopher Wren. The exterior dome of this fine building, which is constructed of oak-timber, supported by a brick cone arising from the same base, sustains on its top a stone-lantern, weighing the enormous quantity of 700 tons. The pressure in such cases is propagated along the cone in the direction of the slant-side, and that, too, equally throughout, so that no part can have an inclination one way or another more than the rest. The familiar fact of the great compression that may be made on an egg, when held lengthwise between the hands, may serve as an illustration. Besides the hoop at the base of this dome, there are hoops in different courses of the cone, which secure it, and at the same time cause it to press quite vertically on the piers. Indeed, altogether, the constitution of this dome, and the arrangement of the other parts of the building, so as to correspond with it, display the greatest judgment. The dome is represented in Plate 12. Fig. 11. from Mr Nicholson's work before alluded to; and the following explanation cannot fail to interest the reader. A A a a A A, is the dome of brick already mentioned, two bricks thick, and having, at every rise of five feet, a course of excellent brick of 18 inches long, bonding through the whole thickness. This dome, it may be remarked, was turned upon a centre, of the nature of which we shall soon have occasion to speak, and was afterwards beautifully painted by *Sir James Thornhill.*

B B b b B B is another cone of bricks, one foot six inches thick, and this is also painted. Part of this cone may be seen through the opening at a a, by a person standing on the floor of the church. It is on this cone that the timber work is supported, the horizontal beams C C, D D, E E, F F, being tied into G, H, I, K, by means of iron cramps.

The diameter of the dome is 104 feet, and there are 32 trusses in the circumference; but the scantling of none of the timbers, it ought to be remarked, is so great as is to be found in many churches. The stairs which lead to the golden gallery at the top of the dome, are carried between the trusses of the roof. The sides of the dome are segments of circles, which, if continued, would have formed a pointed arch at the top; on which is built the cupola of Portland stone, 21 feet in diameter, and nearly 64 feet high.

The dome of St Peter's church, in Rome, designed by Michael Angelo, is nearly an ellipsoid externally, having the longer axis perpendicular to the horizon. It rises perpendicularly from its base, where it is very thick. At the height of 50 feet, the vaulting divides into two, gradually separating from each other, but connected by thin walls dovetailed into each shell, and thus forming a very stiff covering. There is an elegant stone lantern on the crown of the dome. If this dome had been of the same size as that of St Paul's, it would, from the manner in which it is constructed, have been at least five times as heavy; but it is so well supplied with iron bars, and other contrivances, that no doubt can be entertained of its durability. It has long been the admiration of the world, and would itself have established the character of the artist.

The dome of the Pantheon at Rome, still extant, is the oldest of which we find mention in history. It was built in the reign of Augustus, and, like all the ancient Roman domes, is a much less portion of a sphere than a hemisphere. It terminates in an opening, called *the eye.*

Next in antiquity to the Pantheon, but greater in fame, is the dome of St Sophia, at Constantinople, erected in the reign of Justinian. Its early misfortunes were ominous of its fate, and the ruin of the eastern empire. Anthemius, a Greek architect patronized by the emperor, undertook to erect a dome over the church that had been raised on the ruins of a former one built by Constantine, which should surpass the boasted grandeur of the Pantheon. He wished, by a natural enough ambition, that the cross might triumph over the Pagan world, and the greatness of the object called forth all the energies of his mind, and the accumulated experience of his art. The church itself was in the form of a cross, and it was vaulted with stone. Ten thousand workmen are said to have been employed in it, and it was finished within six years after laying the foundation. No wood was used in its structure, except for the doors, the remembrance of former calamities having excited strong apprehensions of the agency of fire. The dome was raised on a ring formed by four pillars placed at the angles of a square, about 115 feet from each other, and arched over, and having the angular spaces fixed up so as to constitute a complete circle. Additional securities were sought. Four walls, nearly solid, running longitudinally, two from the south, and two from the north sides of the pillars, from the distance of about 90 feet, were intended to resist the pressure of the east and west arches; and besides this, these arches were abutted upon by half domes, resting on cylindrical walls, capable, it was believed, of resisting the pressure of the north and south arches. In this last office four columns of Egyptian granite assisted. But all was insufficient, as a few months after its completion, the dome gave way on the east side, carrying with it the contiguous semi-dome. Isodorus, who succeeded Anthemius on his death, made an unsuccessful attempt to aid the original plan, by filling up some vacuities. The new dome gave way before being quite finished, and also on the east side. A third time was it constructed, with farther help from buttresses, and the greatest care to have the structure made light, by employing pumice-stone, in place of more ponderous materials, and keeping the walls slender, &c. Even these precautions, it seems, would have proved ineffectual, if the arches on the north and south sides had not been filled up with new ones of smaller size, in three stories. Some visible fractures in the arches shewed the necessity of such assistance. It is clear, that the architect of this extraordinary edifice, who was allowed to be the first of his time, was not well acquainted with the scientific principles of dome vaulting. If he had, there cannot be a doubt that he would have secured the base by hoops, so as to render the pressure as much as possible a perpendicular thrust. In this respect he has been much surpassed, and with perfect security, by both Michael Angelo and Sir Christopher Wren; and perhaps any common architect, in modern times, would be sure to avoid the blunders committed in this clumsy building.

Arnolfo Lusii projected a dome for the cathedral at Pisa, but dying two years after, no architect could be found to execute it according to the original plan. It remained unfinished for more than a century. Then, in a consultation of the principal architects of Europe, Philip Brunelleschi, a native of Florence, intended at first for the bar, but whom nature destined for this profession, asserted the possibility of erecting a double cupola, with sufficient room for a staircase between to reach to the top; and consequently gave in a proposition to that effect. This was conceived absurd, and in fact an insult on those who had assembled. He was accordingly dismissed with indignation, and had, for a time, to bear the sarcasms of his brethren. But as none of them offered any thing suitable for the purpose, the persons who had the management of the building were induced to pay some regard to his device, and at last to agree to an attempt at its execution. Some conditions were imposed on him, and, in the first instance, an ignorant assistant. Getting free of him shortly, he proceeded in his plan, and at last accomplished it, though the lantern with which he purposed to crown the work was not finished in his life time. This cupola is octangular, 154 Flemish cubits in height, and the lantern, of which Brunelleschi left the model, 38 cubits; over this is a ball and then a cross, the whole being above 200 cubits in height, which is greater than had ever before been attempted on such a plan. Its dimensions, indeed, are greater than those of any of the Roman domes, with the exception of St Peter's.

The very remarkable wooden dome of the Halle du Blé at Paris, which was destroyed by fire some years ago, merits description. Its construction, invented by a carpenter of the name of Molineau, was extremely simple. It occurred to this man, that a thin shell of timber might be made so as to be nearly in equilibrio, and also, when firmly hooped horizontally, to have all the stiffness that was requisite. His project was submitted by the magistracy of Paris to the consideration of the Academy of Sciences, by whom it was favourably entertained, the members being highly pleased with the justness of the principle on which it was founded, and at the same time surprized that it had not been thought of before. The circular ribs comprising this dome, consisted of planks nine feet long, 13 inches broad, and three inches thick,—three such planks, bolted together so that two joints met, forming each rib. All the pieces being small, no machinery was required for carrying them up. The ribs were connected together by horizontal timbers, and iron straps, which answered the purpose of hoops. When the work had reached a certain height, every third rib was discontinued, and the open space was glazed. At a certain height above this, again, every second rib was discontinued, and the vacancy in like measure glazed. Higher up, still, the heads of the ribs were framed into a circular ring, so as to form a wide opening, and over this was placed a glazed canopy, in which was left a space for the escape of heated air. This dome, which was 200 feet in diameter, and only a foot thick in the sides, was extremely beautiful, and used to be spoken of with admiration by all who had seen it.

The chief objection to wooden domes, is their incapacity to sustain great weights. Wherever this is required, it is evident that we must have recourse to trussed frames similar to those we have already described; for it would be absurd to trust to a mere shell which could not fail to be crushed in at the top. There are not many cases, therefore, in which they are useful.

Mr Bunce has lately invented a dome, which we shall describe in the words of Mr Nicholson: "In this construction, all the abutting joints are continued in uninterrupted vertical planes; but the horizontal joints of every two stones break on the middle of the stones on either side; so that every alternate stone of a course projects upwards, and leaves a recess for the insertion of the stones of the next course. Upon this principle, the intervals, as the building approaches nearer the top become more wedge-formed, and, the interior circumference being less than the exterior, the stones can be inserted only on the outside; consequently, if made so exact as just to fit into their places, they cannot fall inwardly. This mode of joining stones may be convenient, as requiring no centering; but unless the courses be nicely equilibrated, it is more liable to burst than when a dome is constructed in the ordinary manner, since every row of stones, from the base to the top, forms an arch independent of the rest."

The octagonal pyramids, which constitute so remarkable a feature in Gothic architecture, are to be understood on the same principles as those of domes. They are very firm though thin, and certainly exhibit much science. Our spires and steeples are of this description, and these, it is well known, are extremely various in form and magnitude.

It is obvious, then, that great freedom has been taken with the principle of equilibration, whether well or ill understood. Few persons will doubt, we believe, that accident or whim has done more to discover it than science. It is extremely improbable, indeed, that the generality of the artists who have excelled in this way, were so profoundly conversant with mathematics as to be able to deduce their practical rules from its abstract speculations. Yet the whole theory is capable of the strictest demonstration, and has actually obtained it from some learned men. We hold it quite foreign to our purpose to enter on such a task, and shall content ourselves, therefore, with a very few additional remarks of a less abstruse nature.

The stability of the dome is in general much greater than that of an arch, and, on the whole, is easier obtained. The dome also, as we have seen, may be left open at top, in which it differs from the arch. Even the equilibrated dome, which is the weakest, will admit of this; and it will admit also another building to be laid above it, as a lantern, provided the weight of this addition be not greater than that of the circular segment of the dome that is left out. If the curve of the dome be flatter than the curve of equilibration, the load it will sustain may be increased above this amount. Lastly, almost any load whatever may be laid on a dome in the shape of a truncated cone, or one in which the contour is convex towards the axis, provided the base be secured by a hoop in the way formerly mentioned.

Domes are generally intended for ornament. They admit of immense variety in form, so as to suit every fancy. Those of a concave exterior, which are often seen in Gothic buildings, particularly when vaulted over with circular sweeps, have an uncommonly pleasing appearance. Domes, in general, are lighter than any other covering of the same area; and as they allow of cylindrical intersections in every direction, spring gracefully from any polygonal surface, and may be broken off at any height, they must be considered as possessing very eminent advantages in the higher departments of architecture.

Sect. III. *Of Centers.*

The term center is used to denote a mould, or frame, generally constructed of wood, by which the materials of vaults or arches are supported during their erection, and from which they receive their particular shape.

In common cases, as where the space to be arched over is small, and admits of intermediate points on which carpentry work can be raised, the construction of centers is attended with no material difficulty.

Any of the frames or trusses used for roofs will be sufficient for carrying the weight and establishing the shape desired. The principles formerly explained, therefore, of the abutment of rafters, the prevention of their lateral secession from each other by tie-beams, &c. are here in full force; and some very inconsiderable modifications of external form, which can be readily attained by the same means, or the addition of merely shaped timbers, are all, in general, that such occasions require. Much more urgent are the demands when the span is wide, the weight of materials consequently great, and when, from the height of the arch, or the intervention of deep water, continually navigated perhaps, no intermediate support can be procured. Such a case calls for the greatest solicitude, and is an opportunity for displaying the utmost invention and science of the artist. Here every thing must rest on the piers, or sides, and the centre or frame, by which the materials of the arch are to be supported, must itself be an arch, dependent on the relations of its constituent parts. Common workmen, not aware of this, are in the habit of heaping timber on timber, with little regard to any thing but the ultimate form, as if strength consisted in quantity merely, and there was no danger to be feared from the very weight of the pieces which they were so awkwardly combining together.

The mechanical principles already explained will lead us to more judicious, and, at the same time, less expensive and less hazardous constructions.

As the utmost strength of which the materials are capable may be necessary in this nice art, it must always be remembered to place them in such a manner that they shall not be subjected to any other strain than what is in the direction of their length. This, we know, may be in two ways, compression and tension. The former is always to be preferred where it is practicable, as in the case of the drawing of timber, the material to which we are now chiefly alluding, reliance must be put on the manner in which the beam is united at its ends with other pieces, and this is almost necessarily a weak security. Sometimes, indeed, it is impossible, or at least very difficult, to avoid ties, and they are accordingly to be seen in good specimens of carpentry. But an unskilled workman can scarcely be trusted with them, and even the highest artists ought to employ them with the greatest caution, and as seldom as possible. Universally, it is of essential consequence to know whether a piece be acting the part of a tie or not, that if it be, the requisite securities may be afforded it; and no piece ought to be introduced without a thorough examination of the nature of the strain to which it is likely to be subjected. Even the occasional variations which may and will occur during the progress of the work, especially from what is almost sure to happen in some degree or other, the sinking of the arch, ought to be guarded against to the full extent of professional foresight.

Thus far of the strength of centers. They must also be so stiff or immoveable, that no weight that can be laid on them shall vary their form. Suppleness, supposing it consistent with strength, which it may be, is an essential imperfection in a center, and must be obviated by the proper employment of struts, which will hinder any change in the angles of the pieces. It is an important practical maxim for a structure of this kind, in which changes of pressure are almost continually taking place, and very often without allowing time for new contrivances, to make the timbers capable of undergoing both the sorts of strains now mentioned. Nothing indeed is more usual than for the same piece to be subjected at one time to compression, and at another time to be liable to be drawn asunder. But it is certain, that, with the exception of the pieces which immediately sustain the parts of the arch, and which may be perfectly accommodated, each to its own share, all the requisite timbers may be placed so as that none of them shall be exposed to a transverse strain. The strength of the timbers, it is almost needless to say, must be estimated according to the circumstances of the case and the quality of the materials. And with respect to the relative position in which they are to be placed, it is proper to observe, as aiding in this estimate, that it is the upper part of the arch which presses most on the frame. This will be very obvious, indeed, when it is considered, that each archstone to be supported, inasmuch as it lies on an inclined plane, has a tendency to slide down in proportion to its relative weight; or, in the language of the mathematician, that its weight is to its tendency to slide down the plane on which it is supported, as radius to the sine of elevation of that plane.

No rule perhaps can be given for determining the absolute pressure in different arches. On the whole, there is room for concluding, that, in those that are circular, and of a high pitch, about two-thirds of the weight are borne by the center before the key stone is laid on, and that in arches which are either elliptical or low pitched, the proportional weight to be sustained by it is greater than this amount. The nature of the curve, therefore, must be considered in adjusting the magnitude or dimensions of the pieces. In all cases, it is obvious, the greatest attention is required in securing the abutments of the center, on which the stability of the whole ultimately depends. Where the nature of the space to be arched over will admit, it is always preferable for this end, that the entire opening be divided into two or more spaces, and that supporters be raised up, properly secured, on which, in addition to the piers, the center may be erected. In such cases, fewer timbers and less complicated workmanship are needed. But such aid, as has already been noticed, cannot always be had; and often indeed, even the advantage of a long tie-beam is unattainable, from the circumstances of vessels passing, or the liability of a river to be greatly augmented in size by tides or heavy rain.

Examples.—We now proceed to describe different kinds or examples of centers, premising only what the intelligent reader will have already understood, that the strength and stiffness of all of them are ultimately to be found in the triangular frames or trusses into which the centers, however complicated, may be resolved.

Various principles have been adopted for the construction of centers, by different artists, some of them deserving particular notice.

That adopted by M. Hupeau for the bridge of Or-

Construction

leans in France, is one of the boldest ever executed, and is, at the same time, a very simple piece of carpentry. It may be considered as in fact one large truss spanning the entire width, supporting at its top the upper part of the arch, and having its rafters occupied as foundations for smaller trusses, on which the other parts of the arch are sustained. The reader who has attentively considered the principles of construction formerly laid down, will easily comprehend the general nature of this center from the view given of it in Fig. 1. Plate 13. But that we may not mislead him into unqualified praise, it is requisite to say a few words on the history of this case. The arch is 100 feet span, has a rise of 30 feet, and the arch stones are 6 feet long. The architect died when only a few of the first courses of any of the arches had been laid. M. Perronet succeeded him, and completed the work. As it advanced, the vertex of the center rose a good deal, and on being loaded, sank as much. This shewed the weakness of the frame, and that its lower parts especially, were giving little assistance. The two long beams, a d, f g, which form the diagonals of the quadrangular spaces a b c d, e f g h, were therefore added to it, when it became sufficiently strong. These pieces are nearly in the line (continued) of the lower beams, and certainly quite alter the nature of the frame, bringing it to the state, as we have called it, of one large truss, consisting of two long rafters, and a short straining beam placed horizontally between them. The former, it will be seen, are trussed up about their middle, so as to form the side frames, and the latter constitutes the summit of the center. Some additional means were found requisite to support the center during the course of the work. It is certainly far from being entitled to be held as a perfect performance, nevertheless it is an admirable example of what simplicity and attention to the elementary rules of construction are able to accomplish.

Centers may consist of two trusses independent of each other, one supporting the crown of the arch, and the other the sides, or haunches, as they are called. Of this kind was the frame employed by the illustrious Michael Angelo, for the nave and transepts of St Peter's church at Rome; and on the same principle, a little modified, are two centers proposed as a lesson by M. Pitot, a member of the Academy of Sciences. A few remarks on these examples may prove amusing as well as instructive.

A person of the name of San Gallo is said to have constructed Michael Angelo's center. It is a judicious performance, and abundantly effective, erring rather indeed in an excess of strength, and the employment, consequently, of an unnecessary quantity of timber. It is shewn in Fig. 2. and will be easily discerned to be divisible into two parts, of which the superior sustains the greater weight. We agree with Professor Robison, that the innermost polygon, that is to say the lowermost one, is superfluous, as no strain can force in the struts which rest on the angles. The triangle immediately resting on it is pretty much in the like predicament; and one might imagine that the artist thought the king-post acted as a pillar and not a tie, so that he judged it requisite to secure the tie-beam against cross strains from it.

2

In Fig. 3. is represented one of M. Pitot's proposed centers. It is so simple as to be readily comprehended, and has great merit. With the exception, perhaps, of the principal stretcher, which extends the whole width of the arch, a little above the middle, all the pieces that are any way essential to the construction are subjected to one kind of strain, viz. that of compression; and this, as we have already noticed, is an excellence of the highest value. This center is proposed for an arch of 60 feet span. Some objections may be made to it, but we do not think it necessary to state them. Of its sufficiency we have no doubt. The other center proposed by the same person for an elliptical arch, and used by him. we believe, in the middle arch of the bridge at Lille-Adam, being 80 feet span, and rising 31, precisely corresponds with it, and need not therefore occupy our attention. They are both, perhaps, inferior in simplicity and strength to the first one described of this class.

The next examples we shall give are of a more complicated construction. The principle is that of inscribed equilateral polygons. In this, each truss, which consists of a number of struts, placed end to end, so as to form a polygonal figure, stretches over the whole space between the piers. When arranged, the angles of one such truss occur in the middle of the sides of that which is next to it, and so on alternately, till as many such polygons are erected as seem sufficient for the purpose. The trusses, it is certain, may be quite independent of each other, and even when combined together, have been supposed to operate as if they were so, and that in consequence the full amount of their separate agency is thereby obtained. This is very problematical; but, at all events, it has been found expedient to have them united, whatever be the precise mode in which their action is realized. By the nature of the construction, it will readily be conceived, the angles of the alternate trusses are situate in lines pointing towards the center of the curve. In consequence, king-posts, consisting of two beams, one on each side of the truss, and embracing the truss-beams between them, are placed in this direction, pointing towards the center. Other contrivances, which it is unnecessary to particularize, are employed to effect a secure junction; and it is imagined, that, when loaded on the top, the whole will gradually, but conjointly, be brought to sustain the pressure. Perrault, a physician, is said to have invented this construction; but the principal artist who has availed himself of it is Mr Perronet, the architect employed for the bridges of Cravant, Nogent, Maxence, and Neuilly, in which cases it was adopted. They differ from each other in several respects, as accommodated to peculiar circumstances, and seemingly in order to remedy those deficiencies which experience pointed out. We have, therefore, represented the whole of them; but we must confine ourselves to very general remarks.

Fig. 4. is that of Cravant. The arches in this case are elliptical, of 60 feet span, and 20 rise, and the arch-stones were four feet in thickness. The whole weight of the arch was about 558 tons. Though the center was perhaps superabundantly strong, it nevertheless yielded a good deal, and consequently re-

Construction

quired some management in order to have its shape preserved.

Fig. 5. A. represents half of the center for the bridge of Nogent, being an arch of 90 feet span and 28 rise; arch-stones $4\frac{1}{2}$ feet thick, and the unreduced load on each frame nearly 235 tons. It cannot be doubted, that this center, from the dimensions of the timber used in its construction, was vastly stronger than was needful.

Fig. 5. B. shews half of the center used at the bridge of Maxence. The span in this arch is about 76 feet, and the rise little more than six. Its appearance, therefore, is disagreeably flat, and will probably seldom have imitators. The center is a very judicious one of its kind.

Fig. 6. is a delineation of the center employed in the bridge of Neuilly. Here the arch is 120 feet span and 30 rise, the arch-stones being five feet thick. This center was strong enough, but much too flexible. It consequently yielded and twisted very remarkably at different periods of the work. This ought to have been foreseen; for it is quite manifest that the angles of the trusses throughout are vastly too obtuse. Fewer pieces ought to have been employed. This would have required the angles to be acute; the feet of the lower trusses, too, it may be observed, would have been much better placed at a lower part of the pier. This last remark applies generally to M. Perronet's centers, in all of which the feet of the trusses are too short and narrow. It is, on the whole, very unlikely that his practice in this and in several other points will be adopted in our country, where a much better model is to be had, as we shall immediately show.

The center to which we now allude is that which was used at Blackfriars bridge, London, by Mr Mylne. Its principle is perfectly simple, that of supporting different points of the arch by trusses, consisting of two legs or rafters, the feet of which rest on the piers, one on each. The rafters have an intermediate piece, called an apron piece, applied at top, which is useful both for strengthening the exterior joints, and giving stiffness to the ring on which the stones are laid. This will all be easily understood from Fig. 7.

The rafters, or legs, consisted of several pieces firmly abutted together, and occasionally secured, moreover, by double king-posts; but sometimes where they intersected, they were halved into each other. This last mode has been objected to, as tending to weaken the beams; but it seems to be almost necessary, owing to the frequency of the intersections; and at all events, it is certain, from the nature of the construction, as well as the dimensions of the timber used in this case at least, (the legs being 12 inches square,) that the center was abundantly strong and perfectly firm. As an evidence of this, it is proper to mention, that not the smallest sinking or twisting was observed in the progress of the work, and that the whole sinking of the crown, before setting the key-stones, did not amount to one inch. Greater security than this, surely, is not desirable; and if we except the consumpt of timber, which is certainly considerably greater than in M. Perronet's centers, no reasonable objection can be made to this plan. The reader will observe, that the upper part of the center, where, of course, great support is needed, is fully accommodated to its office by the simple truss of equal legs extending from side to side; and that though, in the lateral points, particularly those that are low down, one of the legs of the truss is very oblique, this disadvantage is compensated for by the nearly upright position of its antagonist. The principal arch in this bridge, it ought to be mentioned, is 100 feet span, and its height from the spring 43 feet, the arch itself being above 6 feet in thickness. The center employed in Westminster bridge, Fig. 8. was constructed on a very similar principle, which, it cannot be doubted, is perfectly suitable to arches of any width.

Other centers have been proposed, and sometimes adopted, but we do not think it necessary to particularize them. Those we have mentioned are sufficient for the general purpose we have in view, of putting the reader in possession of elementary knowledge. We cannot conclude this part of our subject without noticing a recent proposal for a center of a very different kind from any hitherto employed. It is the invention of Mr Telford, but, as far as we know, has never yet been adopted. This gentleman, according to a printed report of a committee of the House of Commons, on the most effectual mode of improving the mail roads in Wales, &c. recommends a cast-iron bridge to be laid across the Menai, a small arm of the sea, dividing the island of Anglesea from Caernarvonshire, through which the tide runs with considerable velocity, and which is constantly navigated by pretty large vessels. In furtherance of this advice, Mr Telford proposes a single arch of no less than 500 feet span, 100 feet in height above high water at spring tides, and 40 feet in breadth. The nature of the bottom of the channel, the depth at low water, and the great rise and rapidity of the tides, render the common modes of centering from below very difficult, if not impossible. A plan then is devised for accomplishing it from above, which as far as can be understood from the description afforded, has a plausible enough appearance. It is impossible not to admire the ingenuity and boldness that could suggest so stupendous an undertaking; and if it shall be found practicable, it can scarcely be doubted that it will give rise to more magnificent structures in this department of architecture than the world has yet seen.

Striking a center.—A few words on the mode of striking a center, as it is called, will finish what seems necessary for the general reader on this part of our subject. To separate the scaffolding from an arch, so that it may not receive any material alteration from the want of support, is a nicer operation than most persons might at first imagine. This will appear from a few very simple observations on the state in which the arch stones rest on the centering, and on one another. We have already noticed that they are mostly supported on the center, previously to the adjustment of the key-stone. But they are not all equally so. The lower courses lean much more on one another, and those which are towards the crown, on the other hand, are nearly altogether sustained by the center. Besides this, the

Construction. mortar used for connecting them is but little compressed during the continuance of support from the center, and least of all, of course, about the upper parts; and if much time has been occupied in the work, it must necessarily be in different degrees of consolidation. It follows, then, that an instantaneous and total removal of the support, would be productive of irregular, and, in fact, irremediable settling; probably, indeed, the upper stones would fall out, and the whole arch be destroyed. The gradual removal of the center, therefore, seems plainly dictated; and it is no less obvious, that it ought to take place first from the lower parts of the arch, or, at least, in such a manner that the natural process of abutment which takes place amongst the different courses may be secured. Various plans have been adopted. "The best method," says Mr Nicholson, "is to let the center down all in a piece, by easing some of the wedges, (introduced between the centers and beams on which they rest, and employed for this purpose;) to let it rest there for a few hours, in order to try whether the arch makes any efforts to fall, or any joints open, or stones crush or crack, that the damage may be repaired before the center is entirely removed, which is not to be done till the arch ceases to make any visible efforts." M. Perronet was in the habit of cutting away the blocks, or bridgings, as they have been named, on which the arch-stones immediately rested, beginning with the lowest on each side, and advancing gradually upwards, but rather quickly, till all that had been put out of shape any way, by the bending or shrinking of the center, was quite detached. The haunches, now unresisted, pressed inwards, and, of course, harder than formerly, on the arch-stones which were nearer to the crown. When this had taken place for some days, he proceeded, but with greater caution, to destroy the blocks under those upper stones. This always produced some degree of shifting, and towards the end seemed to occasion a very irregular curve, and a good deal of rising and sinking, against which he had to employ several cautionary or remedial measures. The former method, which with sundry modifications is generally practised in this island, is vastly to be preferred, and the happier fortune of our artists is the most satisfactory test of its superiority. Mr Mylne's process for accomplishing this delicate and important business was peculiarly excellent. The view given of the centre used by him at Blackfriars bridge, already described, shews the pieces concerned in it.

Sect. IV. *Of Bridges.*

Bridges are the most remarkable examples of the use of the principles of the arch, and merit, from their beauty and advantages, the most attentive consideration.

Wooden bridges.—We commence with those which are built of wood, between which and the examples of centers just now given there is a close and obvious connexion. The rules recognised in their structure may be easily traced to the general principles formerly detailed, and need not, therefore, occupy much attention at present. But the following preliminary remarks will be found of utility to some readers.

There are two ways in which a piece of timber, A B, Plate 12. Fig. 11. may be supported at C, its middle point, where it is exposed to greatest stress in its position across a river. 1. It may be suspended by ropes, &c. &c. as D C, E C, from two fixed points D E, above it; or it may be propped up on the ridge of two rafters, as d C, e C, resting on two fixed points, d e, below it; and, 2dly, It may be connected with a point that is so supported, either by suspending it by a king-post, as F C, coming from the ridge of two rafters, as A F, B f, or by resting it on a strut, as C F, which itself is supported by two ropes, as A f, B f.

Whichever way be adopted, it is very evident that the support is the more powerful as the angle formed at C, by lines drawn from these points, is the more acute. Either plan may be strong enough; but the first case requires greater extent of space; and besides this, it may not always be convenient to find adequate points of support either above or below the beam; whereas the second, requiring no other fixed points than A and B, is always practicable. This second method, therefore, is most commonly adopted. Room, in short, can always be found for the simple truss A F B. As the length of the king-post does not add to the support of C, it may be proper to find two points, as a and b, in Fig. 12. at a moderate distance below A and B, from which to erect the rafters, and to employ a shorter king-post. If the parts A C, C B, of the beam A B, are conceived still too weak, though by this means its strength is vastly increased, it may be further aided by trussing each half, as is shewn in Fig. 13. which is a very simple, but at the same time a very strong, and rather neat construction for a bridge, the intersections of the secondary braces with those of the main truss forming an agreeable appearance of a hand-rail. The beam A B may be made of two pieces, having a certain inclination to each other, and forming such a structure as is given in Fig. 14. Another mode of supporting A B is shewn in Fig. 15. in which F G is supposed to be one-third of A B; and sundry modifications and combinations may be practised with advantage, as is to be seen in Figs. 16. 17. 18. These plans, though very simple, which, indeed, is a great commendation, afford room for skill in the adjustment of the dimensions of timber, and are susceptible of strength and accommodation sufficient for a considerable width. They have been frequently used in Germany, where their durability is promoted by the judicious practice of covering them from the weather by means of wooden roofs. "We have seen," says Dr Robison, "a bridge of 42 feet span, formed of two oak trusses, the biggest timber of which did not exceed six inches square, bearing, with perfect steadiness and safety, a waggon loaded with more than two tons, drawn by four stout horses."—"Another, in the neighbourhood of Stettin, had a carriage road in the middle about 20 feet wide, and on each side a foot-way about five feet wide. The span was not less than 60 feet, and the greatest scantling did not appear to exceed 10 inches by 6. This bridge consisted of four trusses, two of which formed the outside of the bridge, and the other two made the separation between the carriage-road and the two foot-ways."

If the width of the river be too great to be accomplished by one truss, then several trusses may be combined together by simple addition, like the arch-stones of a bridge, as is shewn in Fig. 19. Here the frames A, B, C, D, are to be considered as separate bodies, supported by mutual abutment; but the construction is different from that in which the pieces act, as we have seen, on the principles of carpentry, and in our opinion is inferior to it, though sometimes abundantly serviceable. It may be greatly strengthened by the addition of pieces operating as ties, as already described; in which case, it is very advisable that one of the polygons into which it is divisible should contain the whole abutments, and the other should consist altogether of ties. This may be understood from Fig. 20. in which the polygon A B C D E F, consisting of two layers of beams, (one being supposed too weak,) contains the abutments, and the other, A b c d e F, may be nothing more than an iron rod. The whole has a kind of distant relation to the Norman roof, and this, in fact, may be often rendered a very convenient construction. So much for the general principles. The following descriptions will supply some information as to particular contrivances.

Cæsar's bridge.—Of ancient wooden bridges very scanty relations are found in classical authors. Palladio and others have made drawings from Cæsar's description of the bridge by which he conveyed his army over the Rhine. It seems to have been a clumsy piece of workmanship, formed by the very inartificial mode of driving piles into the bed of the river, and connecting them together by cross-beams and transverse pieces, over which hurdles were placed. It scarcely merits attention in point of science.

To the same writer, Palladio, we are indebted for an account of a much finer structure over the Cismone, a river at the foot of the Alps, which divide Italy from Germany. It is described as a single arch somewhat more than 100 feet wide, entirely suspended by the framing which forms its sides. Palladio has given several plans for wooden bridges, and specifies three ways in which they may be constructed without having posts driven into the water.

Schaffhausen bridge.—A very remarkable wooden bridge was erected across the Rhine, in the canton of Schaffhausen, by a plain uneducated carpenter, named Ulrick Grubenhamm. A stone bridge which had been erected at the same place, having suffered injury from the river, fell in 1754. This man proposed a wooden bridge as a substitute. After some hesitation, natural enough to the managers, the plan was adopted, and executed in 1758. The descriptions given of its dimensions, it is to be regretted, are contradictory, and, unfortunately, the bridge itself is no longer in existence; it was destroyed by the unsparing hands of the French in 1799. Another bridge on the same plan, and built either by the same person or his brother, at Wittengen, also in Switzerland, seems to have been confounded with it. Indeed, the accounts of them are not easily reconciled. The entire length of the former, we are told, was 364 feet (the width of the river being, according to Nicholson, 390 feet,) and its breadth eighteen feet. The artist wished to make only one arch, but was positively enjoined by the magistrates to use one of the remaining piers of the former stone bridge, as an intermediate support. This he so far complied with, as to divide his bridge into two unequal parts, both, we are told, apparently resting on this old pier. Though this bridge, it is said, was able to sustain the greatest loads, yet it would tremble under a single passenger. It is said, moreover, to have been eight feet out of the straight line, having its angle pointing down the river. The distance from this angle to the abutment nearest the town was 171 feet, the other position being 193 feet. From the last mentioned circumstances, it seems that the pier at the angle was really a point of support.

The bridge at Wittengen is reported to have been of one arch, 230 feet wide, and, as such, was still more extraordinary. Professor Robison, writing on the authority of Mr Coxe, who slightly describes this bridge in his Travels in Switzerland, says, the rise was twenty-five feet, certainly low enough for the width, and Mr Nicholson, on the other hand, (why, we do not know,) reduces it to five, which must, we apprehend, be a mistake. The road-way, it is proper to mention, was suspended between two parallel arches, having something of the catenarian curve, and built of seven courses of solid oak logs, in lengths of twelve or fourteen feet, and upwards of sixteen inches thick. The logs, we are further informed, were selected as naturally suited to the intended curve, and were not any way trimmed by cutting across the grain. The same artist and his brother were concerned in the construction of several bridges of this sort.

Wooden bridge in America.—The ingenuity of Grubenhamm, undoubtedly very great, was surpassed by a person of the name of Bludget, who has constructed a wooden bridge over the river Portsmouth, in North America, of one arch, 250 feet span. The principle is an improvement of what has now been described; and so confident was the artist of its strength, after this trial, that he is reported to have said he would trust such an arch of four times the width. It is difficult, indeed, to set limits to such efforts and skill.

Wooden bridges in Britain.—We have no example of wooden bridges in this country worthy to be compared with those now spoken of, at least in respect of magnitude. But from smaller specimens, of equal, if not superior principle, it is not to be doubted that our architects are as able to excel in this as in any other department of the profession. We ought particularly to mention the following specimens: The wooden bridge over the Clyde, at Glasgow, built by Mr Nicholson, and intended only for foot passengers, displays great judgment. It was finished in 1804, and consists of nine openings, each of them 42 feet wide. The river, where it crosses, is 387 feet in breadth. Since its erection this bridge has sustained several very high floods without any way yielding. Its appearance is elegant, and but a small quantity of timber is used in its construction. Somewhat on the same plan is the bridge at Walton-upon-Thames, the production of Mr Etheridge. The centre arch is 130 feet wide and 28 feet in height. There are good examples of wooden bridges between Chelsea

Construction

and Battersea, Fulham and Putney, Brentford and Kew, all over the Thames.

The bridge over the Don, about seven miles from Aberdeen, constructed somewhat differently, by Mr James Burn of Haddington, is highly to be commended. It is 109 feet wide, rather more than 13 feet rise, and 18 in breadth. This ingenious artist has erected bridges on the same principles in other parts of Scotland. As a pattern, we have given a view of the first-mentioned in Plate 14. which the reader, it is believed, will easily comprehend.

Stone bridges.—An interesting history of ancient bridges might be given, but would contribute little to the object we have now in view, the elucidation of important theoretical principles. The Greeks, admitting them to have been acquainted with the nature of an arch, did not apply it to this use. The Romans were more expert in the practice of this art, and have left some monuments of very judicious bridge building. China abounds in them. But we prefer more modern examples, and especially such as have been erected since the art has been cultivated under the qualified influence of mathematical principles. We shall merely mention, therefore, some of the more remarkable ancient bridges, occasionally noticing their most striking features.

Roman bridges.—In Rome and its vicinity were eight bridges, some of which, and the vestiges of others, are still extant under different names.

The bridge built by Trajan across the Danube, which was destroyed by Adrian to prevent the passage of barbarians into the empire, was one of the most magnificent ever erected by the Romans; but the descriptions given of it are somewhat discordant.

The finest bridge, perhaps, that was built by that people in Italy, is said to have been that at Narni, connecting two mountains between which flowed the river Nera. Its whole length was above 600 feet, which was divided into four arches, the largest of which was 142 feet span. The *Pont du Garde*, a Roman structure about nine miles from Nismes, is very remarkable, as serving the double purpose of a bridge over the Gardon, and an aqueduct for supplying Nismes with water. It is described as consisting of three series of arches, one above another, to the height of 190 feet, and is built of very large stones bound together by iron cramps without cement. There is a noble bridge at Lyons, of Roman origin, 800 yards long.

Over the Tagus, at the city of Valenza de Alcantara, about 25 miles from Madrid, is a bridge which was built in the time of the emperor Adrian. This superb work is 670 feet long, divided into six arches, and its height is more than 200 feet.

The bridge on the river Guadiana, in the province of Estremadura, is reported to have 64 arches, and to be 1300 paces in length. Perhaps the largest stone arch in existence is that of the bridge of Brioude, in the lower Auvergne in France, ascribed to the Romans. The span is 181 feet and the height 68 feet.

The bridge of Avignon is of more recent date, having been finished in 1188. It was 1000 yards long, and consisted of 18 arches, some of the ruins of which still remain. An arch of 160 feet span was built at Verona in 1354.

Construction

Modern bridges in Italy.—Italy abounds in bridges of comparatively modern date. The Rialto in Venice, a city which, from its peculiar situation, has more bridges than any other, is rather singular. It is a single arch nearly 100 feet span and only 23 in height. Michael Angelo designed it, and it has always attracted great notice. Its breadth, which is 43 feet, is divided into three small streets, by two rows of shops in the middle, in the center of which is an arched opening where the three streets communicate. Dallaway says, that the most perfect bridge he had seen was one at Florence, of three arches, each 100 feet wide.

In Portugal.—Portugal may boast of its aquæduct bridge, near its capital, as one of the noblest works of the sort ever executed. Its total length is 2464 feet, and it consists of 35 arches, the eighth of which being the largest is 108 feet span and 227 in height. It was finished in 1732, nearly 20 years after its foundation.

In France.—We have elsewhere spoken of some modern French bridges, and have shewn several of their centers. France has many more bridges well deserving of attention. Those of Blois, consisting of 11 arches, the center one being 91 feet span,—of Mantes on the Seine, of three arches, the largest being 128 feet span, and the other two 115 each—and of the Loire at Saumur, which has 12 elliptical arches of 60 feet span each, justly claim this distinction. A bridge mentioned by Mr Nicholson, which is not very unlike the last named, though greater, and erected at Moulins, over the river Allier, and consists of 13 semi-elliptical arches, 64 feet span each, also merits notice.

In Britain.—Great Britain is not defective in this part of architecture. Several bridges of an ancient date testify the exertions of her former inhabitants; and those of modern times may vie with the productions of her neighbours.

The bridge at Croyland in Lincolnshire, supposed to be the oldest structure of the kind in the island, is a singular work. It is formed by the meeting of three segments of a circle in a point, a circumstance imagined to allude to the doctrine of the Trinity, which is not unlikely, considering the period when it was built, viz. about the middle of the ninth century. It is still very sound, and exhibits but few marks of decay.

London bridge, commenced in 1176, required 33 years for its completion. It originally consisted of 20 arches; but two of them were turned into one in 1758. It is a cumbrous building, and is evidently unworthy of the dignified position it maintains. A more suitable companion has been projected for the bridges of Westminster and Blackfriars.

About the same period were built the bridges of Rochester over the Medway, and at Newcastle-upon-Tyne. The former is 550 feet long, consisting of 11 arches. The latter was broken down by a flood in 1771. At Burton-upon-Trent is a bridge erected in the 12th century; it is 1545 feet in length, and is the longest bridge in England. It has 34 arches.

One of the arches of York bridge is 82 feet wide and 27 feet high.

At Winston in the same county, is a single arch bridge nearly 109 feet span. It was built in 1762 for L.500. Llanwst bridge in Denbighshire, was designed by Inigo Jones in 1636. It has three circular arches, the middle one 58 feet span.

The most singular bridge in the island is over the Taaf, in Glamorganshire, executed by a country mason of the name of Edwards. It is a single arch 140 feet span, being the segment of a circle of 175 feet in diameter; its height is 35 feet, and its greatest breadth only 11 feet. In Mr Malkin's *Tour in South Wales* will be found a very interesting history of this extraordinary work.

Of Westminster and Blackfriars bridges over the Thames, certainly the noblest structures of the kind in England, it seems unnecessary to say more. For the sake of comparison it may be merely mentioned, that the former, which was quite completed in 1750, consists of 13 large and two small arches, of a semicircular form, and the middle arch is 76 feet span; and that the latter, which was finished about twenty years afterwards, has nine elliptical arches, and the middle arch is 100 feet span. They are both nearly 44 feet in breadth.

In Plate 14. is exhibited a view of the Strand bridge over the Thames.

A magnificent aquæduct bridge over the Lime, at Lancaster, was constructed by Mr Rennie. It has five arches, of 70 feet span each, is 57 feet in height, and the canal which crosses it admits the navigation of barges of 60 tons burden.

Of bridges in Scotland, the following particularly merit attention.

The Gothic bridge over the Don, near Old Aberdeen, was built in 1281. The arch is 67 feet span, and 34½ in height.

The bridge of Perth, on the Tay, is 906 feet long, divided into nine arches, (besides a land-arch,) the middle one being 77 feet span, and its breadth 26. Mr Smeaton executed it between 1760 and 1771. The same artist, much about the same time, constructed a good bridge over the Tweed at Coldstream, and another over the North Esk, near Montrose, both of them inferior to that at Perth.

The North Bridge at Edinburgh, built by Mr William Mylne about 1770, is remarkable as having no water below it. The full length of this bridge is 1125 feet, but the length of the piers and arches occupies only 310. Its three great arches are about 72 feet span each, and two smaller ones 20 feet. The entire height to the top of the parapet over the center arch is 65 feet, and the breadth about 42 feet. The arches are semicircular, rising 36 feet from the spring. The bridge has a perceptible rise from the middle towards the south end, which, being injudiciously accommodated by the bending parapet, impresses with the notion of the middle arch having yielded, which is not the case.

Kelso Bridge, over the Tweed, constructed by Mr Rennie, has an uncommonly fine appearance, and does great justice both to the artist and the situation. The arches are elliptical, five in number, each being 72 feet span, and the rise 21 feet. The road-way is quite level; and some ornaments of a modest character give no small degree of elegance to the whole bridge.

Near the junction of the Teviot with the Tweed, is a bridge over the former, built by Mr Elliot of Kelso, which has also a fine effect. It is of three arches, the middle one being 65 feet span.

A bridge between Dunbar and Berwick-upon-Tweed, known by the name of Pease, or Peathsbridge, is somewhat singular. It consists of four semicircular arches of different spans, from 48 to 55 feet, crossing a gulley, or hollow, the bottom of which is 124 feet below the surface of the road.

An arch over the Den Burn, at Aberdeen, is the largest in Scotland. It is 130 feet span, and second only, we believe, to that over the Taaf. As originally proposed by Mr Telford, it would have been 150 feet, surpassing any in the kingdom. But prudential motives induced the magistrates of the town to adopt the smaller scale.

At Tongue-land, in Kirkcudbright, is a fine arch, designed by the same able artist, 118 feet span.

A bridge over the Spey, at Fochabers, constructed by Mr G. Burn, has four arches, the two middle ones of which are 95 feet span each.

The bridge at Dunkeld, built a very few years ago, is reckoned the finest in Scotland. It consists of five large arches and two small land ones, the middle of the former being 90 feet span. Somewhat strangely, Mr Telford's claim to the merit of its design and construction has been disputed, and, indeed, publicly denied in the newspapers, by a Mr Brown of Jedburgh. As far as we know, there has been no reply on Mr Telford's part.

Several bridges of various descriptions are either erected, or about to be executed in Scotland, under the management of a board of commissioners appointed by Parliament.

Ireland has but few good bridges. Sarah's bridge, at Dublin, is among the finest. It consists of one arch 110 feet span. Essex bridge, and Carlisle bridge, in the same city, are respectable productions.

Iron-bridges.—Some account of iron bridges will naturally be expected in this place. They are beyond all question of British origin, and hitherto, we believe, have been exclusively constructed in this island. Their use will likely be extended to other countries where the material can be obtained so readily as to render them economical. The principles on which they are formed may be easily understood from a description of the chief examples.

The first iron-bridge was erected at Coalbrookdale, in Shropshire, in 1779, by Mr Abraham Darby, iron-master at that place. It consists of a single arch 100 feet 6 inches span, and is composed of five ribs of three concentric arcs each, which are connected by radiating pieces, and which pass through an upright frame of iron at both ends serving as guides. Plates of cast iron cover these ribs, and sustain the road-way. The weight of iron used in this bridge was 378½ tons. The abutments are of stone. As a first attempt, this is a very meritorious structure; but it is faulty in several respects, and has been surpassed by later efforts.

According to Mr Nicholson, the second iron-bridge

Construction

was cast by order, and agreeably to the design of Mr Thomas Paine, of political notoriety, who intended it for America. As he failed to pay for it when constructed, the manufacturers, who had taken it up to Paddington, near London, employed its malleable iron in the formation of Bishop Wearmouth bridge, near Sunderland.

The iron-bridge at this place, which was erected between 1793 and 1796, under the management of R. Burdon, Esq. assisted by Mr Thomas Wilson as engineer, and Messrs Walker of Rotheram, the founders, consists of a single arch 236 feet in span, 32 in breadth, and 100 feet high from low water. In this bridge, blocks of iron, consisting of a kind of frame-work, were used in place of key-stones, each weighing about 4 cwt. A series of these blocks, to the number of 105, formed a rib, six of which composed the breadth of the bridge. On these were laid diagonal bars, extending to the abutments, to prevent the swerving of the ribs. Cast-iron rings, diminishing in size from the ends towards the middle, fill up the spaces between the arch and the road-way, which consists of a strong timber frame covered with cement and a bed of marle, &c. This magnificent and yet light fabric required 260 tons of cast iron and 46 of wrought iron, and cost L.27,000. Vessels of 200 tons burden can pass below it in full sail, while its strength is sufficient for any incumbent load. A view of it is given in Fig. 9. Pl. 13.

A cast-iron bridge was designed by Mr Telford for Buildwas, on the Severn, and was finished in 1796. It is 130 feet span, and employed $173\frac{1}{7}$ tons of cast iron.

There is one at Staines, over the Thames, considered the neatest and most complete up to the period of its erection. The arch is 181 feet span, and is formed much in the manner of that at Sunderland.

Boston, in Lincolnshire, has an iron bridge 85 feet span.

There are two at Bristol, each of 100 feet span.

Mr Telford designed a bridge for an arm of the sea, between the counties of Ross and Sutherland, in Scotland. The arch is 150 feet span.

We have elsewhere spoken of the proposal of the same engineer for an iron-bridge over the Menai; and we ought to mention, that he proposed another, of no less than 600 feet span, in the room of London bridge. Of the practicability and advantage of such plans, we have not the smallest doubt. Indeed, the almost incompressible nature of the material, the facility with which it can be brought to any desired shape, and the readiness with which it admits of connexion, being considered, in subserviency to the improved principles and matured judgments of such artists as we have named, it would be almost presumptuous to speculate on the probable limits to the practice. The sole difficulty, perhaps, lies in the centering necessary for very stupendous bridges. Time and ingenuity, we are convinced, will overcome this; and new agents, hitherto unthought of, will come to our aid, to falsify the puny conjectures of timid or ignorant men.

Draw-bridges are generally made of wood, sometimes of iron, or of both together, having stone abutments, and are employed on canals, or in fortifications. They are differently constructed. Till lately it was most usual to have them to lift up and let down by means of hinges, and the aid of a kind of balance, operating vertically. But it has been found more convenient to make them turn on a center horizontally, so that the leaf or fold of the bridge is always kept in the same plane. Such bridges are called *swivel* bridges. The best examples are at the West India and London docks. The entrance to the wet dock at Leith affords an example on a small scale.

PART III. OF STYLE, AND THE PRODUCTION OF EFFECT.

Of Style.

Importance of Architecture.—Architecture has been sometimes denominated the chief of the mechanical arts. To this distinction, the important benefits which it confers on mankind, the magnitude of the materials which it employs, and the skill required in its nicer operations, may justly entitle it. The degrees and the manner in which it is practised, form very striking characteristics of the improvement of different countries; and the durability which attaches to its productions has contributed to secure and perpetuate the reputation of people long since vanished from the world. In most of the merely useful arts, the wants of the present generation alone are contemplated and supplied. They minister to individuals, and to circumstances, indeed, which may often occur in the compass of a single life. But the architect, on the contrary, looks into futurity, and provides for the welfare and pleasure of distant ages. His works are destined to abide the judgments of persons yet unborn, any one of whom may have a right to bestow praise or censure equal to that of the original possessor. No wonder, then, that he seeks the establishment of his fame by the adoption of imperishable principles, or endeavours to consecrate it by the authority of laws which are universally recognised. Utility is the first object he aims at, and constitutes, indeed, the only but sufficient excellence of which many buildings can boast. The want of it, we may affirm in general, can be redeemed by no other quality.

Becomes soon ornamental.—But architecture, unless among savage nations, is not long confined to the creation of simply useful edifices. The love of ornament is natural to our species; and, accordingly, human ingenuity seldom stops in the acquisition of mere clothing, or the erection of habitable but uncouth dwellings. Decoration speedily, often immediately follows, and is therefore attempted, and successfully too, in one way or other, by every society of mankind that has emerged from the barbarism of nature. Its kinds are no doubt various and discordant, but the object is the same.

Certain peculiarities in the materials themselves, which have been employed in both of the arts now mentioned, appear to have given the first impulse and gratification to this powerful propensity, and to have served long afterwards as the respected basis of fashion and the guide of taste. Thus the use of skins and fur as ornaments in dress, prevails in the most civilized countries; and the accidental, perhaps the cumbrous appendages of the wooden huts inhabited by the primitive Greeks, are still copied in the practice of the most elegant architecture of modern Europe.

In this art, innovation is indiscriminately condemned. Some monuments of ancient skill, accordingly, which have survived the wreck of time, and the revolutions of the world, and on which, it must be allowed, the mould of age has bestowed a sanctity of character not easily withstood, are held up exclusively as the standard of excellence, from which there can be no appeal to reason or convenience.

From the admiration of ancient architecture have sprung the metaphysical doctrine of "proportions essentially and necessarily beautiful." And "where, asks the student, are these to be found?" "In the Greek orders to be sure," replies the zealous advocate for the doctrine, immediately launching out into extravagant commendations of a few hackneyed examples; "and these orders, (he continues,) have always been admired, always will be admired, and, in short, nothing else can or ought to be admired."

Can it be supposed, that the wretched log-houses of a nation of barbarians have been the precious idols of the *cognoscenti* for some thousand years; that it was held little short of heresy or sacrilege to hesitate in paying them homage; and that it is only in our own days that an individual has publicly dared to dispute their title to such extraordinary veneration? Yet all this is true; and the clear explicit renunciation of so monstrous a delusion, ought to be the preliminary step in any elementary treatise on architecture considered as a fine art.

By such a step, then, we are enabled altogether to exempt a curious and highly interesting subject from the absurdities in which it has commonly been involved, and to avoid the parade of technical rules, and a conceited phraseology, which never failed to perplex the judgments and exhaust the patience of former enquirers. Here we shall avail ourselves of the remarks of a well known critical journal on Mr Alison's Essays on Taste; and this we do the more readily, because it displays those fundamental principles in the essays themselves which are most intimately connected with our present subject, and will consequently furnish the reader with the most important light necessary for its satisfactory investigation.

"There are few things about which men of *virtu* are more apt to rave, than the merits of the Grecian architecture; and most of those who affect an uncommon purity and delicacy of taste, talk of the intrinsic beauty of its proportions as a thing not to be disputed, except by barbarian ignorance and stupidity. Mr Alison, we think, was the first who gave a full and convincing refutation of this mysterious dogma; and while he admits, in the most ample terms, the beauty of the objects in question, has shown, we think, in the clearest manner, that it arises entirely from the combination of the following associations: 1st, That association of utility, convenience, or fitness for the building; 2d, Of security and stability, with a view to the nature of the materials; 3d, Of the skill and power requisite to mould such materials into forms so commodious; 4th, Of magnificence, and splendour, and expense; 5th, Of antiquity; and 6thly, Of Roman and Grecian greatness." "This analysis, (it is added,) is to us perfectly satisfactory. But, indeed, we cannot conceive any more complete refutation of the notion of an intrinsic and inherent beauty in the proportions of the Grecian architecture, than the fact of the admitted beauty of such very opposite proportions in the Gothic. Opposite as they are, however, the great elements of beauty are the same in this style as in the other; the impressions of religious awe, and of chivalrous recollections coming in place of the classical associations which constitute so great a share of the interest of the former. It is well observed by Mr Alison, that the great durability and costliness of the productions of this art, have had the effect, in almost all regions of the world, of rendering their fashion permanent, after it had once attained such a degree of perfection as to fulfil its substantial purposes." "Buildings, (he observes) may last, and are intended to last for centuries. The life of man is very inadequate to the duration of such productions; and the present period of the world, though old with respect to those arts which are employed upon perishable subjects, is yet young in relation to an art which is employed upon so durable materials as those of architecture. Instead of a few years, therefore, centuries must probably pass before such productions demand to be renewed; and, long before that period is elapsed, the sacredness of antiquity is acquired by the subject itself, and a new motive given for the preservation of similar forms. In every country, accordingly, the same effect has taken place; and the same causes which have thus served to produce among us, for so many years, an uniformity of taste with regard to the style of Grecian architecture, have produced also among the nations of the east, for a much longer course of time, a similar uniformity of taste with regard to their ornamental style of architecture, and have perpetuated among them the same forms which were in use among their forefathers, before the Grecian orders were invented." *Edinburgh Review, Vol.* 18.

Chap. I. Of Different Styles of Architecture.

We now proceed to a slight sketch of the styles of architecture alluded to in the preceding remarks, commencing with the Greek orders.

Sect. I. *The Greek Orders.*

The term Order in architecture has been variously defined. It signifies much the same as method, or arrangement, and is applied to such a portion of a certain building as comprehends its entire design. Columns, whether curved or square, these latter being called pilasters, are generally chosen to indicate this design, and, in consequence, the word order has been chiefly appropriated to the arrangement or display of their proportions. It is, in short, a system of the dimensions and ornaments of columns and pilasters, as producing a form capable, for reasons already

Of Style.

assigned, of exciting agreeable or pleasing effect. Differences in these dimensions and ornaments, or, more correctly speaking, differences in the proportions of the parts, constitute various orders, each of which has its peculiar character, and is, consequently, appropriated to a certain purpose or design.

The invention of orders is ascribed to the Greeks, and the language employed to describe their members is borrowed from that people. But certain circumstances would lead to the idea, that the Greeks themselves had been indebted to the Egyptians for some of the fundamental principles of the system. One thing is very clear, that the nature of the orders, whether originally Grecian or not, manifests them to have been the result of observations on the wooden huts of an early people. This can be easily shewn.

Let us form a hut, suppose in a country abounding with wood sufficient for the purpose. The size of the timber will greatly modify the nature of our intended habitation. But we shall imagine that we have it of dimensions capable of affording much strength and security, and that we want a house for the accommodation of a large family. We propose, therefore, to fix a certain number of good sized posts in the ground, at equal distances from one another, so as to form a regular shape, say a square, or other four-sided figure. Within this space we can arrange similar pieces and branches, either resting on the posts or twisted round them. But we are chiefly anxious about a covering at top, to guard us from the rain, &c. to which we are often exposed; and, besides this, our posts, though very secure below, are liable to move a good deal at top, in consequence of having no connecting medium. We must contrive a remedy for the evil, and make a roof. The first step is very simple, and leads us towards the whole of our object. We fix certain pieces longitudinally on the tops of our posts, connecting them firmly together, so that one cannot be moved without affecting the rest. On these again, and across the breadth, or narrower dimensions of the inclosed space, we lay other pieces and probably another row, across these too, for the greater certainty of defence. Still we find that the rain penetrates, and that our roof is incompetent to our wants. It is an obvious suggestion of reason, that certain pieces of wood, or flat stones, meeting in an angle in the middle, and sloping down over the sides of our hut, will carry off the water from it, so that the interior may be kept dry. Thus, then, with various modifications, which peculiar circumstances and views will indicate, we have succeeded in the fabrication of a comfortable abode; and thus, in fact, we have ascertained the origin of those famous orders which are still held as the models of classical architecture, though the materials on which the art now operates are essentially different, and might justly be expected to require another more appropriate treatment. Substitute the term column for post, or tree, and the term entablature for roof, or covering, and the mystery of the orders is disclosed. We shall specify the members into which these parts are divided, and which are common to all the orders, and afterwards take notice of some distinctions in the orders themselves.

The column is divided into two parts, the shaft and the capital, the former meaning the body of the column, from the base or foundation where its rests, to that portion towards the top, where it is usual to have mouldings or ornaments, and to which the name of capital is applied. To these two parts it is now very usual to add a third, viz. the base, though some consider it separately, and subject it also to a certain division.

The entablature, which we may conceive as the roof, or weight to be sustained by the column, is divided into *architrave*, or *epistyle*, that part which rests immediately on the capital; *frieze*, or *zoophorus*, above the architrave, and a little receding from it; and, lastly, the *cornice*, being the upper part which projects beyond the frieze, answering apparently to the jutting ends of the roof, as the architrave does to the lintelling beams, and the frieze to the intermediate crossing ones.

All of these parts both of the column and entablature, we ought to remark, are variously subdivided, as may be seen in Fig. 1. Plate 15. to which we refer as abundantly satisfactory, without occupying more room with verbal descriptions.

Properly speaking, there are only three orders, named from the places where they are conceived to have been invented, the Doric, Ionic, and Corinthian. To these many modern authors add the Tuscan and Composite.

All these orders have the same chief members, and are similarly subdivided. The proportion of their members, the ornaments attached to them, and the destinations for which they are intended, differ in each, as we shall soon explain. But, first, it will be advantageous to the student to give a rule for drawing an order. This we shall take, with some modification, from a small but judicious practical work, by Mr P. Nicholson, entitled the Student's Instructor in drawing and working the five orders of Architecture, which we recommend to his notice.

Rule for drawing an order.—Make a scale of the diameter of the column, as represented in the plate last referred to; divide it into six equal parts, or modules, as they are called, and the first of these into ten equal parts, or minutes. Every member of the order is to be reckoned in minutes of this scale, whether in height or projection, in the following manner. Draw a perpendicular through the middle of the column, on which set off all the heights. Draw another line parallel to this one, at the distance of twenty-five minutes from it, forming the diminution, on which set off the upper projections, as shewn in the figure. Those of the base are to be set off from the outer extremity of the column, which is thirty minutes from the axis. A slight examination of the plate will be sufficient for the understanding of this rule. The names of the mouldings, with their proportions in minutes, are marked on the side of the column. For an account of their varieties, and particular rules for describing them, we refer to the work now mentioned, as more necessary for the student than likely to interest or be valued by the general reader. Most of the practical works treat of this subject with a wearisome minuteness. We shall not add to the number, or occupy any room in specifying the differences of the Greek and Roman proportions of the orders, our object being the most elementary information.

Doric order.—This is the most ancient of the Greek orders, and seems to have been the only one known in Greece till the time of the Macedonian conquest. It bears, more than any of them, perhaps, decisive marks of the common origin of the orders, as may be seen by the peculiarities of its frieze and corners, indicating the joists and rafters of the wooden hut. This will be very plainly discovered in Fig. 2. Originally it seems to have wanted a base, and the columns were often fluted, as if for the convenience of resting the spears with which the early Greeks were in the habit of arming themselves, both circumstances very characteristic of high antiquity. From an examination of many monuments of this order, Mr Nicholson, in his Dictionary, lays down the following remarks as to the proportions of its parts: 'For public buildings the columns may be five diameters (the standard being the diameter of a section of the shaft at the bottom,) or five diameters and a half in height, and for private dwellings, six; the diminution may be one-fourth of the inferior diameter. The height of the capital may be two-fifths of the lower diameter, and may be divided into two equal parts, one of which may be given to the abacus (see the former figure,) the other to the echinus and annulets (that is, the ovolo and fillets of the capital,) the latter may be subdivided into five equal parts, and four of them taken for the echinus, and the remaining one for the annulets. The height of the entablature may also be divided into four equal parts, of which one may be given to the cornice, and the other three being subdivided into two parts, one part may be given to the epistylium, and one to the frieze or zoophorus." It ought to be remarked, however, that the ancients admitted considerable license in determining the proportions. We shall now mention the most distinguishing peculiarities of this order.

The capital consists of a large convex moulding, in the form of a bow, and a square stone, apparently intended to keep off the rain. The architrave, which represents a wooden beam, is formed of a single piece of stone or marble, and is furnished with a projecting band at top. From a small fillet under part of this band, there hang six *guttæ*, in imitation of so many drops of rain, which may be imagined to have proceeded from the *glyphs* or channels in the frieze immediately above. These glyphs, which are three in number, in consequence of which they are generally called *triglyphs*, correspond to cuts supposed to be made in the ends of the beams, for the purpose of draining off the rain, and are formed by two planes meeting internally in a right angle in each of them. The spaces or pannels between these triglyphs, generally of a square shape, are called *metopes*, and are often ornamented with heads of animals and other figures. Over the triglyphs are placed what correspond to the ends of the rafters, denominated *mutules*, one being over each, and one also over each metope. The cornice projects greatly, and its corona usually forms a very well marked distinction between its upper and lower parts. The columns in this order, which diminish from the bottom to the top in a curve or a straight line, are very often fluted in a manner peculiar to itself. The flutes are usually twenty in number, without fillets, and terminate under the annulets of the echinus of the capital. Many examples of Doric are still extant, and have been described in various works. One of the completest, though not the most ancient, is that of the theatre of Marcellus at Rome, described by Sir William Chambers, in his valuable work on Civil Architecture. But the finest specimens are to be sought for in the remains of Greek buildings, as displayed, for instance, in *Stuart's Athens*. In the purest examples, generally speaking, the architrave and frieze are nearly of equal height, each being commonly equal to the upper diameter of the column, and the mean height of the cornice is half the diameter, so that these three parts are to each other in the proportion of 3, 3, and 2; the face of the tablet in which the triglyphs are placed and that of the architrave are in one vertical plane, and the vertical face of the architrave projects beyond the superior diameter, but is retired within the inferior one.

Ionic order.—The Ionic order is next in antiquity to the Doric, and in all probability had its origin in the desire of novelty which so certainly besets a people among whom luxury has commenced. But to what particular object of imitation its capital, by which it is chiefly distinguishable, was conformed, we are not now able to ascertain. Vitruvius, whose authority has been pretty extensively owned, asserts it to have been intended for a representation of the curls in the female head-dress; according to others it is copied from the bark of trees dried in the sun. The forms of certain sea-shells, of the horns of rams, and various other bodies, are also reported to have given the hint.

The divisions of this order are the same as in the former, but the general appearance is lighter and more simple. This is owing to the greater length of the column, which may be stated at 18 modules, that of the Doric being 16, and to the entablature being less encumbered. On the whole, it may be remarked, the parts of this order have not been so strictly defined as the corresponding ones in the Doric, an argument, by the bye, for the notion, that it was more the creature of fancy. The most remarkable peculiarity in the capital is what is called the *volute*, which is easily known by its shape resembling, it is conceived, the curls of the hair as they hang on the right and left sides of the head. The cornice, besides, is characteristic of this order equally with the capital. It represents the ends of the laths to which the tiles were attached, and which are called *dentiles*. But some of the remains of this order, found at Athens, are destitute of these marks. This order has not the triglyphs or mutules of the Doric.

In all the specimens of Greek Ionic, the height of the cornice, measured from the lower edge of the corona upwards, seems to bear a constant proportion to the entire height of the entablature, viz. nearly as 2 to 9. The frieze is wanting in almost all the Asiatic examples of this order. The height of the column has been somewhat increased by the moderns; and in works intended for grand effect, it is usual to make the height of the entablature at least one-fourth that of the column, though in general it amounts to two diameters. See Fig. 3.

Corinthian order.—It is uncertain when this order was invented, but there can be no doubt that it is of much later date than the others we have described. It is remarkable for its delicacy and susceptibility of ornament, characters which have obtained for it the title of *virginal* order, in contradistinction to the Ionic, which, from its greater sedateness and simplicity, has been denominated *matronal*. It is in the capital that the decorations of the order are so conspicuous, and this, according to an ancient report, is said to have been copied from an appearance noticed by an Athenian sculptor in passing the tomb of a young lady. A basket, covered with a tile, had been placed upon it, and round this an Acanthus spread its leaves, the tops of which were bent downwards in the form of volutes, by the resistance of the superincumbent tile. This hint is the commonly reputed origin of the order, and certainly has pretty good claims to be so considered. But it was not in Greece that this order attained the greatest perfection, or was most employed. The Romans excelled in this respect, and in some periods of their history seem to have almost confined their ornamental architecture to it.

According to Vitruvius, the shafts of the Corinthian and Ionic columns have the same symmetry, and the only difference between their entire columns is in the heights of their capitals, the former being the whole diameter of the shaft, and the latter only one-third. He makes the Ionic column eight diameters; the Corinthian, therefore, would be eight diameters and two-thirds. But the moderns have increased it to ten diameters, in which the base and capital are both included. The shaft is usually fluted when the entablature is enriched,—but not when it is formed of variegated marble. The number of flutes and fillets is the same as in the Ionic, generally twenty-four; and the lower parts of the flutes are often filled up with cables to about one-third of their height. In place of cables, some fantastic artists employ flowers, ribbands, &c. but this taste deserves the epithet of vulgar; indeed cables themselves are not quite pure. The Ionic entablature is often applied to this order, but an appropriate one has sometimes been attempted, and a cornice, in particular, is specified as most suitable. It consists of several members, for the due effect of which the whole height of the entablature requires to be increased more than two diameters, making it two-ninths of the columns, whereas, when the Ionic cornice is used, a fifth of the height of the column is sufficient. We cannot help thinking with Mr Nicholson, that this latter is more in proportion to the slight columns of the order.

Sir William Chambers was of opinion that this order was employed by the ancients in temples dedicated to Venus, Flora, Proserpine, &c. "because the flowers, foliage, and volutes, with which it is adorned, seemed well adapted to the delicacy and elegance of such deities." But the Romans do not appear to have restricted it to such purposes, employing it occasionally in temples dedicated to Jupiter, Mars, and Neptune. Indeed it is questionable if the ancients in general were particularly careful to suit the character of the style to the nature or object of the building. We find, in reality, perhaps, all the orders indiscriminately used for all purposes, and on all occasions. See Fig. 4.

The Tuscan and Composite orders, which, from the circumstance of their having been introduced in Italy, are commonly called Roman, may be considered as mere modifications of the three just now described, and require little notice.

Tuscan order.—The Tuscan order has been called *gigantic*, on account of its dimensions and general appearance of strength. It is the simplest of all the orders, having fewest parts and ornaments, and is accordingly used commonly where great weights are supposed to be sustained. No ancient specimens of it, in an entire state, have reached our times, and, in consequence, its proportions, especially those of the entablature, are rather guessed at than accurately determined. Fig. 1. shews the Tuscan.

Composite order.—The Composite order may be said to be compounded of the Ionic and Corinthian. It is rather extensively employed by the moderns—for no other reason that we can discover, than as, from its ambiguous and somewhat undefined character, it allows ample space for the love of novelty. As connected with the orders, we may here mention some other parts of the Greek architecture, before leaving the subject. See Fig. 5.

Pilasters—These are subject to the same rules as columns, from which they differ only in plan, being square or flat in place of round. They are equally suitable for exemplifying the orders, and are similarly distinguished by names. But it is a general opinion, that they are less perfect. As they save room, cost less in construction, and add strength to a building, they are frequently employed either alone or in conjunction with columns.

Attics.—This is a name borrowed from the country of their origin, applied to low square pillars resembling a pedestal, which are placed at the upper parts of buildings as a crown, and generally in order to conceal the roof. Their proportions are not very accurately determined; but it is a pretty common maxim, that their height ought not to exceed one-third of the order on which they are fixed, nor be less than one-fourth.

Colonnade signifies a series of columns, whether separate or connected, used in the support of an entablature, and has its specific name from the number of columns as *tetra-style, octo-style, &c.*

Intercolumniation is the name given to the space between columns. It has been divided into five species, according to the amount of interval, as *pycnostyle*, when the columns were no more than a diameter and a-half from each other, reckoning by the inferior diameter; *systyle*, when at two diameters; *eustyle*, when at two and a quarter; *diastyle*, when at three diameters, and *aræstyle*, when at four, or most thinly set. Other denominations have been applied to the intervals in the Doric order, taken from the

Of Style.

number of the triglyphs which were placed over them, as *monotriglyph* when only one, *ditriglyph* when two, &c. &c.

The term *antæ* denotes a sort of square pillars, which the early Greek architects sometimes placed at the ends of their walls projecting to a considerable distance from the front of the building, so as to form the *vestibulum* or *pronaos* in the case of a temple.

Pediments are ornaments, in imitation, obviously, of the rafters and tie-beam of a wooden hut; a horizontal cornice representing the latter, and two equally inclined pieces, or sometimes more, the former. The moderns seem to have lost sight of this origin, and, accordingly, not unusually commit blunders in the construction of the pediment.

Arcades.—Such is the denomination of certain openings in walls, which, from being too considerable for a lintel, are arched over. They form very good ornaments, and, when well constructed, are stronger than colonnades, for which they are occasionally substituted.

Niche.—The niche is a smaller opening, or recess in a wall, intended for the reception of statues, &c.

The Greeks testified their hatred of the Persians, and their contempt for the inhabitants of Caria, who at one time gave assistance to that people, in a singular manner. They put figures of both under entablatures instead of columns, subjecting them, as it were, to the office of slaves. To these figures the names of *Persians* and *Caryatides* have been applied. Something similar to these are the *Termini*, a kind of half human form, no way more comfortably disposed of. It is not a little strange, that any of the moderns should adopt such perverse absurdities. Extravagant, however, and in the absence of national prejudice, surely unpleasant as this practice is, it illustrates in a very convincing manner what may be held as the only just criterion of the beauty of the orders, their accommodation to the purposes for which they are destined. These figures are evidently put under a burden, aud are conceived as sustaining it. Precisely so do the columns in which the features of the orders are displayed. Their competency to the office is the chief recommendation they can have, and thus Mr Alison's remarks are fully confirmed: "In all the orders," says that writer, "the fitness of the parts to the support of the peculiar weight, or appearance of weight in the entablature, is apparent to every person, and constitutes an undoubted part of the pleasure we receive from them. In the Tuscan, where the entablature is heavier than in the rest, the column and base are proportionally stronger. In the Corinthian, where the entablature is lightest, the column and base are proportionably slighter. In the Doric and Ionic, which are between these extremes, the forms of the column and base are in the same manner proportioned to the reciprocal weights of their entablature, being neither so strong as the one nor so slight as the other. If the beauty of such proportions is altogether independent of fitness, and derived from the immediate constitution of our nature, it is difficult to account for this coincidence; and, as the beauty of fitness in these several cases is universally allowed, it is altogether unphilosophical to substitute other causes for the same effect, until the insufficiency of this cause is clearly pointed out." We shall have evidence of the same truths, in some particulars, in the style we have next to notice. The comparative effects of some of the Greek orders are attempted to be displayed in Plate 16.

Of Style.

Sect. II. *Gothic Architecture.*

The word Gothic seldom fails to summon up notions of stupidity, ignorance, and barbarism. It is very unfortunately applied, therefore, to a style of architecture exhibiting much ingenuity and skill. But no other denomination for it has been generally acquiesced in, and as the inaccuracy of the application in every sense is universally known and admitted, there would be some affectation in any attempt to substitute another in its place.

The architecture so named is that which is to be found in old cathedrals and many other large edifices erected throughout several countries of Europe between the 12th and 16th centuries. It differs widely from the style already described, both in construction and appearance. In the Grecian architecture, the adjustment of materials depended on their strength in large masses, which need only be arranged in neat forms, of simple contrivance. The Gothic, on the contrary, with no other materials than what a Greek artist would have conceived useless, in fact the rubbish and chippings of his work-shop, produced structures of equal strength and perhaps greater magnificence. This triumph over imperfection, it is clear, was not to be obtained without the aid of superior skill that could be called into action in circumstances where the possession of better means superseded the necessity of invention. In appearance, again, this style is easily distinguished by its slender shafts and clustered pillars, its circular, pointed, or angular arches and groins, its spires and pinnacles, and the variety, number, and minuteness of its decorations.

There have been many opinions respecting its origin, all of which have been defended by eminent writers. Those of most note are stated and controverted in a late publication by Sir James Hall. This gentleman, several years ago, excited a great degree of interest by a memoir on the point in dispute, inserted in the 4th volume of the Transactions of the Royal Society of Edinburgh; and the work now alluded to is to be considered as the full elucidation and defence of his earlier speculations. His theory claims the merit of comprehending every part of the style whose origin it undertakes to demonstrate; and, moreover, demands assent, by a direct appeal to history and experiment. We shall not occupy much space in explaining it, as we conceive that a very general view, in addition to some figures, will suffice for such readers as will not be at the pains to examine it more narrowly by a perusal of the splendid work in which it is displayed.

This theory supposes Gothic structures to have been executed in imitation of rustic dwellings made somewhat in the following manner:

In the first place, Let two rows of posts be driven fast into the ground, opposite each other, at an interval equal to that between the posts in the rows themselves, all of them being equal in height to about three of the intervals. Then apply to each post a

Of Style.

set of long flexible rods, thrusting them into the ground at its base and tying them in two places, one a little above the ground, and the other within about a third part of the height, leaving them loose from this point upwards, so that they may be freely moved in any direction. The rods may be three in number to each of the outside corner posts, and five to each of the others, all being placed so as to cover the inside of the posts, and give it the appearance of a bundle of rods. Fig. 6. Plate 15.

"It will be easy now to form the skeleton of a thatched roof. For this purpose, let a rod from each of two opposite posts be bent at its loose tup, so that they may cross each other, as in Fig. 7. which gives us the form of a pointed arch; and the same being done throughout the whole extent of the two opposite rows, a horizontal rod, or ridge-bar, as it is called, being at the same time placed along the points of crossing, we have the appearance of a Gothic arcade. See Fig. 8. Two rods from each post in the same row are now to be treated in like manner, so as to form similar arches in both rows, and these are also to be connected by ridge-bars crossing the longitudinal one. This will be easily understood by examining Fig. 9. without farther description.

We have now employed two rods of each corner post and three of each intermediate one, there still remain one in the former and two in the latter, which we dispose of by causing them to pass diagonally from the corners of each rectangle, not crossing as in the former cases, but applied, side by side, so as to form a continued hoop, or semicircle, as is shewn in Fig. 10.

In this manner all our rods are occupied, and a frame is produced capable of supporting thatch or other covering. "It would seem, however, that, for the sake of strength, the number of rods has been increased in each cluster, by the introduction, between every two of them, of an additional rod, which, rising with them to the roof, still continues its middle position, as they spread asunder, and meets the horizonal pole at an intermediate point. This is shown in Fig. 11. which is drawn with its covering of thatch; and from the imitation of a dwelling so constructed, we may easily trace the three leading characters of Gothic architecture,—the pointed arch, the clustered column, and the branching roof, as exhibited in Fig. 12.

The peculiarities of Gothic windows, doors, spires, &c. are accounted for by the ingenious author on similar principles; and he has actually constructed a small building in this way and with such materials, possessing, in miniature, the features of the Gothic style, and a considerable share of beauty.

The historical evidence adduced, that some such edifices were erected in former times for sacred purposes, will probably influence the judgments of most readers in favour of the theory more than all the acute reasoning and feasible conjectures by which it is supported. But waving every other objection which presents itself to our minds, we shall merely say, before leaving the subject, that this kind of wooden structure, supposed to be the prototype of Gothic architecture, is itself a very complicated piece of work, perhaps too much so for the hasty demands and crude notions of an early people. May it not, then, have been the refined result of attempts to imitate some natural arrangements which afforded shelter to certain primitive generations? A remark, made by Dr Clarke in the course of his travels, will sufficiently point out what we now allude to, and can scarcely fail to yield it some recommendation to the unprejudiced mind. "A building," says that gentleman, in his 2d volume, p. 307. "of considerable, although unknown antiquity, still exists in Rosetta, which seems to afford proof, that the pointed Gothic arch owes its origin to the appearance presented by contiguous palm-trees. The roof is entirely of stone, and consists of curvatures supported by props, representing the trunks of palm-trees, placed in the sides and corners of the structure. Their branches, crossing each other upwards, form intersections corresponding in shape with the pointed arches of our cathedrals." If this notion be correct, it might not be difficult to reconcile the theory with some of the opinions intended to be supplanted by it.

The pointed arch, we ought to observe, is not essential to Gothic architecture. This leads us to notice two species of building to which that very improper title has been applied, both of them to be found in Great Britain, a country abounding in some of the finest specimens of the style. These species have been denominated, by some authors whom we follow here, Saxon and Norman, certainly with some degree of accuracy, if the circumstance of peculiar and almost exclusive adoption by the people so called be allowed to warrant a national appellation.

The Saxon style, or that which prevailed in England before the conquest, but by no means confined to it, and which has been sppposed an adulteration or rude imitation of the genuine Grecian or Roman manner, is characterised by circular arches, such undoubtedly as may be seen in the remains of ancient buildings in Rome, round-headed windows, and massy pillars, also round, and having a sort of regular capital and base. In this style most of the old English churches were built, many of them exhibiting great art, and being productive of very fine effect. A few examples will prove this. In Fig. 13. Plate 15. which represents the arched entrance to the north aisle of the nave of Peterborough cathedral, we have an excellent specimen of Saxon capitals, and of what has been called *chevron-work*, or zig-zag ornaments, often found in Saxon buildings. Fig. 14. same Plate, exhibits one of the arches in the upper walk in the nave of Norwich cathedral. It has what is known by the name of *billet*-moulding, and one of the columns has a spiral band. The window, it will be seen, is in a different style, being pointed, and is of later date. A tower, on the east side of Norwich castle, of great but unknown antiquity, is a beautiful illustration of this style. We have a still nobler example in Durham cathedral, which is in the purest Saxon manner.

The Norman style is distinguished by the pointed arch, and may be considered as that from which the Saxon received its greatest degree of beauty and perfection. It is to this style, particularly, though, as we have already shewn, improperly and inadequately, that the term Gothic has been assigned. It has been divided into the *absolute*, the *ornamental*, and the *florid*; but such distinctions, though no doubt capable of being proved to exist, are of comparatively little moment in a general point of view, and need not occupy our attention in this place. We shall equally disregard the division into 1st, 2d, and 3d orders, which Dr Milner and others have adopted.

The author last mentioned has exhibited, in a series of drawings, mostly taken from Winchester cathedral, the probable rise and progress of the pointed arch. The selection we have made from his work will not prove uninteresting, and may serve instead of verbal description. See Fig. 13.—17. Plate 15. To these instructive drawings, he has added a view of Westminster Abbey, as a good example of the pointed style, contrasted with Durham cathedral, as a specimen of the circular. For particular information on the subjects now cursorily mentioned, we might refer to an immensity of different publications, by which, in various ways, and on various principles, it has been lately attempted to render justice to the skill and taste of our ancestors. It will be enough, perhaps, to specify a Collection of Essays on Gothic Architecture by Warton, Bentham, Grose, and Milner, the 3d edition of which was published at London in 1808; and Dallaway's Observations on English Architecture, London, 1806, in which sufficient references will be found to other valuable productions.

Gothic architecture, originally employed, almost exclusively, in sacred edifices, has, in modern times, been applied either alone, or with various combinations, to the construction of private dwellings. It is questionable if the practice have any advantageous associations to recommend it; and it is very certain, that few instances in which it has been adopted have succeeded in yielding satisfaction as objects of taste. Admitting that they are equally well executed with some ancient structures, still the interest of age is wanting to give them similar effect. But, unfortunately, this admission is not reconcileable with the real condition of most of the modern fabrics denominated Gothic. This term, indeed, seems at last to have obtained in them a suitable exemplar of its common acceptation, and will therefore be continued in general use, we have no doubt, for a century or two longer. To this new application we can have no objections; but then there is the greater necessity for finding another expression to denote the objects which are so miserably burlesqued!

Sect. III. *Of the Egyptian and Oriental Styles.*

We ought not to close the subject of style without making a few remarks on the peculiarities of architecture in some countries which have furnished occasional modes for imitation to the inhabitants of modern Europe. The whole may be classed under two heads, Egyptian and Oriental styles, the latter being divisible into Persian, Chinese, and Indian; to which we may add the Moorish or Saracenic.

Egyptian style.—This can only be ascertained from an examination of ancient structures, the affairs of Egypt having long precluded any attention to this art beyond what is requisite for essential utility. As far as can be discovered, the architecture of Egypt is original, that is to say, unborrowed from the practice of any other country. It is of the greatest antiquity; and some of its monuments still constitute the wonders of the world. The striking features of the style may be said to be massiveness, sameness, tapering walls, huge pillars, flat roofs, and emblematical sculptures. Few and feeble attempts have ever been made to introduce this style into modern practice. Several of its most glaring appearances have of late imposed themselves on public taste in the shape of furniture.

Indian style.—Several resemblances have been noticed between certain buildings in India and Egypt, and hence an argument, in conjunction with other circumstances, for the opinion maintained by very respectable authors, that an intercourse between the two people had formerly existed. It is chiefly in the religious edifices of India that we discover the peculiarities of its architecture, superstition having preserved a partiality for the forms and decorations of early times, whilst political revolutions have proved unfriendly to the cultivation of other branches of the art. The pagodas or temples are of five different kinds: 1. Excavations; 2. Pyramids; 3. Courts of a square or oblong form; 4. In the shape of a cross; 5. Those that are circular.

The excavations are very numerous, and sometimes of immense extent. They are cut in mountains and rocks, and are either plain or enriched with sculptures and statues. The roofs of these singular structures are sometimes flat, and sometimes in the form of an arch, and are occasionally supported by pillars. In the size, the labour requisite for construction, and the general effect they are capable of producing, some of these excavations may vie with the chief productions of art in any part of the world. Those of Elephanta and Salsette, islands near Bombay, and of Vellore, situate 18 miles from the capital of the province of Balagat, are conceived to be the most remarkable.

The pyramids are constructed of large stones, and are rather of a rude appearance. They have narrow entrances and are lighted with lamps.

The most considerable pagoda of the third kind is that of Seringham near Tritchinopoly. It is four miles in circumference, and is composed of seven square inclosures, one within another, the walls of each being 25 feet high, and four feet thick. The outward wall is ornamented with pillars, and the gateways are covered with emblematical figures. Similar edifices are common in India.

At Benares, on the banks of the Ganges, is a noted temple in the form of a cross. The branches are of equal length, and there is a cupola in the middle, under which is an altar sacred to Hindoo mysteries.

Juggernaut is an example of a circular pagoda, several particulars of which must be familiar to most of our readers, from the general attention excited about it by the publication of Dr Buchanan's *Christian Researches*.

Of Style.

The domestic architecture of India presents little interest. We know of no instance in which it has been copied in our regions.

Persian style.—The ancient architecture of Persia, unlike that of Egypt and India, was directed to civil rather than religious purposes. Accordingly, their cities, palaces, and we may add tombs, have been often spoken of in terms of admiration, whilst their temples, that of Belus and a few others excepted, do not seem to have gained much notice. The Persian style has some traces of the Egyptian, the Indian, and the Grecian; and in other respects, again, is somewhat peculiar. The religious edifices which have been erected in this kingdom in modern times, bear strong resemblances to the usual style of Turkish mosques, abounding in domes, minarets or tall slender pillars, squares, &c.

Chinese style.—Very different from any of the styles we have mentioned, is that which prevails in China. It has every mark of originality, and in all probability is directly deduced from the tent. Its form, proportions, and constituent parts, all indicate this early habitation as its prototype. The nature of the government in that country, and the prejudices of the people, have opposed any innovation on their style, and accordingly, almost every species of building exhibits the same general features. It is in the gateways of their cities, and their triumphal arches, which are numerous, that any thing like variety is to be found. Regularity, lightness, and a certain expression of gaiety, are its chief recommendations. Of sublimity, or grandeur, or strength, it can scarcely be said to possess any marks whatever, even on the largest scale on which it is displayed. On the whole, many of its characteristics, with sundry modifications no doubt, may be very judiciously, and with good effect, introduced into our own *country*. They are most suitable to the villa and ornamented cottage.

The *Saracenic*, *Arabian*, or *Moorish style*, if such it may be called, bears some resemblance both to the Egyptian and the Grecian, and probably, indeed, is the result of an attempt made to combine these two together. The finest examples of it are met with in Spain, as the palace of the Alhambra, and the mosque at Cordova, which have been so splendidly illustrated by an ingenious and erudite author, Mr Murphy, whose late work on these remains is perhaps the most magnificent addition to the library of the arts that has been made for half a century. In general effect, judging as we do from this gentleman's drawings, we should imagine that some of these specimens, as the Halls of the Two Sisters, of the Ambassadors, of the Lions, &c. surpass every architectural display that is elsewhere to be met with. This is another, and perhaps decisive evidence, of the truth of our preliminary observations; for it is certain, that in these very examples great departures from what is called *pure taste* may be pointed out. Those who are interested in scenic representations for the theatre could not possibly do better, we should think, than avail themselves of the gorgeous and impressive beauties presented in the superb publication just now mentioned.

Chap. II. Of the Characters of different Kinds of Buildings.

Of Style.

Architecture, we have seen, is both a practical science and a fine art. The former, which is of most importance to human welfare, is the result of observations and experiments on the properties of bodies, and can scarcely be said, notwithstanding the rapidity of its growth, and the perpetual necessity for its exercise, to have attained the perfection of which it is susceptible. The latter, though it has its origin in certain affections of the mind, is and can only be cultivated where civilization and refinement of policy permit a considerable portion of a community to be occupied in devising gratifications for the superinduced desires of the rest. Like the other arts of taste, it is liable to be influenced by the prevalent sentiments and actual condition of society. In some countries, accordingly, where luxury most prevails, there is ground to fear it already hastens towards that state of corruption, from which there seems scarcely a possibility of escape for any thing of human contrivance. The progress of the arts of taste, indeed, has been pretty uniform among very different nations. Simplicity of appearance, and modesty of design, are succeeded by ambitious combinations and conceited artifices; grandeur of effect, and majesty of manner, give place to ostentatious embellishments and useless pageantry. If there be the least hope that architecture shall have another fate, or a more protracted declension, in our times, it must be founded on the prevalence of scientific information enabling great numbers of persons to correct the extravagancies of taste, by frequent appeals to recognised principles of utility. Very fortunately, there is always a sufficient excuse for such appeals, because, as the productions of the art are intended for something else than merely to give pleasure, it is necessary that certain persons should explore the intelligence of the artist, and sit in judgment on his reasons for the conduct he adopts. Their decisions, therefore, are calculated to maintain the authority of laws which are much more respectable than the arbitrary decrees of fashion. The labours of one philosopher, it may be added, incidentally directed towards the metaphysical basis of this art, as we have already mentioned, have gone far to rescue it from a no less hurtful, and, perhaps, more insidious influence. Much still remains to be done for its prosperity; and its fate must ever be held as doubtful, till the extension of science has presented legitimate inducements for the exercise of genius, and an enlarged acquaintance with the fundamental principles of sound criticism shall have lessened men's regard for the imposing, but idle maxims of the schools.

The following remarks on the characters of some kinds of buildings, may not be altogether unacceptable to the liberal-minded reader, as a small but unhesitating attempt to divest the subject of pedantry, and bring it more directly under the cognizance of common sense and feelings than has usually been its fortune to experience. A few observations of a practical nature are occasionally blended with them, which may not at first sight seem quite well placed; but there is a necessity for recurring at times to the primary sources whence the decisions of taste are derived; and we have contrived to avoid repetition, which is less pardonable, by deferring their insertion to this place. We cannot undertake to treat of all the classes of buildings, and have accordingly selected such examples as appeared most susceptible of useful discussion, or more immediately concerned the interests of our readers. We propose, therefore, to treat, 1. Of the Cottage; 2. Of Farm-houses; 3. Of the Villa; 4. Of Grouped Houses; 5. Of Public Buildings. Our observations, we conceive it very necessary to mention, are in great degree the result of our careful perusal of numerous books on the various subjects treated of, some of which we have occasionally specified as more particularly calculated to assist such persons as are interested to prosecute the investigation farther.

Sect. I. *Of the Cottage.*

What is a cottage? There is some difficulty in answering this question. According to Dr Johnson, whose authority may be considered as decisive, it is "a mean habitation." But the word mean is a relative term, and, in the present application, has undoubtedly a reference to a higher or more dignified order of building with which the cottage is compared. The greater house, it is evident, must be supposed to exist in the neighbourhood, or, at least, to be well known by the persons who use the phrase. To an inhabitant of New Holland, it is probable, a moderately neat English hut would appear a superb mansion; and, on the other hand, to a person who had been accustomed exclusively to the elegance of a modern European city, most of the plain though comfortable houses of our farmers might seem to deserve the title of "mean habitations." The definition, then, is a very loose one, and can scarcely be employed without ambiguity or inaccuracy. To deduce an answer from the rank of the person that inhabits a place so called, would be no less unfortunate. The peasant is not its only occupier. Farmers, noblemen, and princes have their cottages, as well as the hedger or ditcher. We must restrict the term, therefore, to something characteristic of the building, if we wish to avoid mistake and to be generally understood. Perfect accuracy in the adaptation of words can scarcely be looked for in this case, and perhaps every reader has attached some peculiar idea to the term. Yet surely there is a common principle regarded in the minds of all who use it. We propose to confine its acceptation to those comfortable country habitations, whatever their form or materials may be, which are of humble size, and unconnected not only with other dwellings, but also with distant outhouses, such as stables, barns, &c. The propriety of this last restriction will be apparent when we come to treat of farm-houses and villas. After all, the term will be found abundantly comprehensive, as including not only the dwellings of the country labourer or farm-servant, but also lodges for gates, hunting-boxes, hermitages, retreats, &c.

The cottage is evidently intended for economy, ease, and convenience. It is remote alike from every idea of expense, grandeur, and danger. It has nothing to do with the circumstances of feudal times, and may be considered as entirely the offspring of improvement and peace. Every thing, therefore, in its appearance, where choice can operate in its creation, ought to correspond with its humble but secure character. But even the lowest examples of this class of buildings have a powerful effect in determining the features of a country, much more indeed, from their number, and the very circumstance of their being destined to accommodate the bulk of the people, than the ambitious and repulsive castles and palaces which are but occasionally met with in a wide sphere. Gentlemen of property would do well to attend to this influence when laying out their estates. Let them never forget, that the rustic beauty of the cottage is one of the finest objects in a landscape, and that the impressions which the mind of a spectator receives from it, are vastly more in unison with enjoyment than any that are obtruded by vast masses of stones, however elegantly or scientifically adjusted. Independent, therefore, of humanity, good taste will suggest some solicitude in the position and structure of the cottage. Nor are there wanting motives of policy to enforce its dictates. The laborious inhabitant of a neat and comfortable cottage, it is certain, will never be without a strong inducement to promote his master's welfare, as conducive to the preservation of his own advantages. We shall give a few directions as to the management of buildings of this class.

Peasant's house.—Every man, having it in his power, would fix on a situation for the abode of his peasantry which seemed to be healthy and to promise comfort. If consistent with the improvement of the prospect and scenery round the principal mansion, though at a respectful distance, the situation is so far to be preferred. A remote hill or rising ground is pleasingly ornamented with a neat cottage or two, especially if their colour have as much liveliness as is compatible with modesty. So sensible are many persons of this, that it is not unusual to plant grotesque and homely fabrics in such situations, though without intending them to be inhabited. These have undoubtedly a good effect, but certainly the animation of children seen at play from a distance, or even the occasional appearance of supported age, awakens an interest of superior excellence. If a valley be chosen for the situation of a cottage, it is adviseable to select a spot of ground that rises somewhat above the rest, and the floor ought to be sufficiently elevated to admit of a drain for the water from the eaves, which is apt to destroy the foundation, besides rendering the dwelling damp, and, of course, unhealthy. It is really painful to see the evil effects of neglecting so obvious a principle as that of raising the floor above the ground, which in general can be accomplished at an expense no way proportioned to the advantages. A cottage on the side of a road requires to be somewhat elevated for another reason; the road itself, in course of time, becomes more raised than it originally was, owing to the accumulation of materials added to it for the purpose of repair.

The addition of a garden is a striking improvement in point of effect and convenience. It is in general better placed in the rear, or to one side of the cottage than in the front, where an inviting and unembarrassed aspect is expected. But an oak tree, a thorn bush, or other umbrageous shelter, is reconcileable with the first and most pleasingly entertained impressions.

The materials for cottages must generally be those which the country most readily affords. In some places we find wood abundant, in others stone is more plentiful; occasionally we must content ourselves with turf or clay, both of which, as has been mentioned, may be rendered subservient to every ordinary purpose. Where brick earth can be had we readily obtain a most useful building substance. Wood enclosures filled in with bricks between the quarters, constituting what is denominated brick-nogging, may be found thrifty and very convenient. If stones are used, the expence of polishing them is highly unnecessary, even where saving is not enjoined by economical considerations, as in the rough state they correspond best with the nature of the intended fabric. The choice of stone, where there is a variety, must be determined by the general principles elsewhere treated of as applicable to particular cases. Bricks are commonly of a fiery red colour, which is offensive to the eye. But this can be easily modified, as we shall immediately mention. The roughest bricks are perhaps the most serviceable in cottage building. A very material saving in them may be made, by leaving the walls hollow, which in slight fabrics of this sort are abundantly secure. They have the important advantage besides, contrary to what might be imagined, of being remarkably warm, as the air included between the shells is a bad conductor of heat. The vacancy may be filled up with gravel, mixed with quick lime and water, of the consistency of whitewash, which will much encrease the strength and durability of the building. Thus a wall fourteen inches thick, for example, may be constructed with the breadth of two bricks, each being four inches in width, having a cavity of six inches in the middle, to be filled up in the way now mentioned, or to be left unoccupied, except by the horizontal and vertical ties requisite for the due connection and stability of the materials. Such a structure, it is very evident, will present a much better opportunity for the judicious adjustment of doors and windows than the common plan, which, by making the walls narrow, requires the frames of both to be nearly on a level with the external surface. This has a flat dull appearance, and the outside window-shutters, which are a very usual accompaniment of it, are still farther destructive of good effect. For this suggestion we are indebted to Mr William Atkinson, whose views of picturesque cottages, published at London in 1805, may be profitably consulted by the reader.

The colour of cottages is not unimportant. Where beauty is easily attainable, or deformity can be conveniently avoided, want of solicitude is at least no virtue. There are several ways of colouring walls. Thus a good wash may be made of lime, in which wet gravel is mixed; where the building is plastered and rough cast, pebbles mixed with lime give it an agreeable broken colour. Lamp or ivory black, a preparation of charcoal, yellow ochre, and various other substances, may be used with lime for the purpose of changing its hue. Lime, or whiting, and some of these colouring substances, mixed with the liquor of boiled lintseed, or the serum of blood, has been recommended with similar intention. Perhaps a light clay or stone colour, not over white, is the fittest for the rural dwelling. Fantastic colours are vulgar and incongruous; red is positively offensive; white hurts the eye, and forms too great a contrast with the adjoining verdure.

Coverings of cottages.—The coverings for cottages may be slates, either blue or grey; tiles differently coloured and shaped; reeds, and thatch. Almost every consideration of comfort, convenience, suitableness, prejudice attaches to the last named material. The chief objection to it is its greater liability to take fire from the sparks of the chimney. But accidents of this kind occur so seldom as scarcely to require a thought.

Thatch is no doubt often dearer than either tiles, slates, or flag stones, which latter are sometimes but owing to their weight very improperly substituted for them. Economy, then, may demand one of these materials. But where thatch can be had more easily, or at the same expence, we should not hesitate to employ it. Let it be laid on in a simple manner, so that it may be readily repaired; its edges ought to be cut smooth, but not too close; and the eaves are to be made to project and overhang a good deal, so as to throw off the water from the foundation. Indeed, with this intention, and as yielding both an agreeable shade and a picturesque appearance, the Chinese snout, as it may be called, is much to be commended. Perhaps nothing more disfigures a house than the opposite of this plan, the bald timid eave which shrinks within the walls. Reeds are a good substitute for thatch, where they can be procured. We have no doubt that other substances might be occasionally used with success, for example willow wands, whins, broom, heather, &c. Grey slate has a pleasing appearance, but is commonly too heavy. Blue slate forms a very unhappy cottage roof, no way harmonizing with the character. The tile, from association of ideas, perhaps answers better. But the red one is very obtrusive, though frequently used. When reduced, as it may be, to a sort of grey colour, the effect is much more congenial. For this purpose, they may be treated with quicklime, sand, and soot, mixed together. A brown colour, which many prefer, is obtained by washing them, before they are burnt, with a solution of the black oxide of manganese. Glazing tiles by means of lead, is most injurious to fine effect.

Windows of cottages.—On the subject of cottage-windows much may be said, because much has been said. People will undoubtedly please themselves when they have the means of gratification, and therefore it seems superfluous to give advice. A word or two may not, however, be altogether thrown away. When simplicity is a constituent of the general character, it is surely most erroneous to introduce any thing under the plea of ornament, which, in any circumstances, would deserve the name of affectation. A form, pleasing enough in itself, or rendered so by some association of ideas, becomes really disagree-

Of Style.

able when it suggests incongruity. Besides the first impression, though, by surprising, it may give delight, is soon lost in the conviction of judgment that follows, and then the taste of the owner and planner is disparaged for ever. Venetian, Gothic, and grotesque windows, are all unsuitable for the simple cottage, though appropriate it may be to a variety of whimsical structures assuming that title. An ancient building, whatever its form or fashion may be, produces an emotion allied to pleasure. But new houses, with old names, expose the absurdity of the contriver. Equally unhappy is the attempt to engraft dignity, or splendour, or solemnity on the thatched dwelling. Finesse and tricks of every kind must not only be discarded but despised. It must have a plain, honest face, without pretensions and without vanity. Rectangular openings, of one, two, or more compartments, supplied with moderately sized panes, or the small-diced glass, as indicative of moderation and economy, answer every purpose of a window, without the possibility of being misconstrued or giving offence.

Form of cottages.—A question has long been agitated, Ought regularity or irregularity to prevail in the form of the cottage? On abstract principles, perhaps, this neither can nor ought to be answered. Regularity is certainly pleasing; irregularirity, on the other hand, implies a degree of ease, the expression of which is agreeable both to ordinary feelings and the design of a cottage. Regularity often becomes stiff; its opposite runs the risque of caprice. The size and situation of the cottage require to influence the decision between them. A very small cottage claims the advantage of regularity to ensure respect. One of larger size may dispense with it, and seek with success the approbation of variety. Uniformity and flatness are unfriendly to picturesque cottages. Numerous broken lines imply stupidity and carelessness, where the subject from its smallness, seems the product of one man and a day.

It is out of our power to give particular plans of cottages, or to lay down rules for the allotment of the various appendages, such as dairy, wash, or brewhouse, piggery, &c. &c. These, of course, are as various as the whims and tastes of professional men and amateurs. We conceive it better to treat of the general principles, with a view to the promotion of comfort and neatness in this very interesting branch of architecture.

Lodge.—The description of the lodge is introduced under this title for various reasons. The only remarks which we deem it useful to mention with respect to it, in addition to what has been already said, are the following: The lodge having a reference marked and well known to the mansion or villa, seems to require at least a character in alliance with it. There can scarcely be a more glaring error than that of making them of opposite or irreconcileable architecture; for example, the house Gothic, and the lodge in the form of a Chinese pagoda; or the former castellated, and the latter pure Grecian. There is no reason whatever for such incongruities; nor, on the other hand, would a perfect but diminutive resemblance be a recommendation. These extremes are easily avoided, and the general principles for the construction of cottages admit of perfect modification to any style of architecture which the chief building may assume. See Lugar's Architectural Sketches for Cottages, &c. Lond. 1805; also Gandy's Designs for Cottages, &c. published at the same time and place; Miller's Country Gentleman's Architect, published in 1810, affords a still greater variety of examples.

Of Style.

Cabâne ornée, or ornamented cottage, a creature of the present times, may either be treated of here or under the head of Villa. Much of what we have already said applies to it. Though admitting, as the name imports, the introduction of something more than is requisite for comfort, yet as one of the most judicious writers on the subject, Mr Pococke, (Archit. Designs for Rustic Cottages, &c. Lond. 1807,) remarks, the various decorations employed in it ought to avoid the appearance of ornament, unless calculated at the same time for some useful purpose, or the more effectual display of natural beauties. Thus the *veranda* yields a shade from the south-west sun; the *trillis* supports the tendrils of the vine, &c.; the porch covers the entrance; a pleasure-ground, shrubbery, water-pond, &c. contribute various advantages for health, recreation, and convenience.

We hold it quite unnecessary to say a word about *hunting-boxes, pheasantries, hermitages*, or any other of the *grotesque* fraternity. They can scarcely be said to be reducible to rule; and perhaps, indeed, if they were so, they would entirely lose their charms in the opinions of those who admire them. It is enough to refer to Mr William Wrighte's treatise on the subject, where the most erratic fancy may meet with ample materials for its operations.

Sect. II. *Of Farm-Houses.*

It is scarcely necessary to say that any house may be called a farm-house which is inhabited by a farmer, and has the usual conveniences around it, for the preservation of grain, and the protection of animals. Necessity converts cottages and common houses of every description into farm-houses. We do not profess to take cognizance of such cases, although some of the following remarks may aid in the filling up of yards with the requisite offices, where economy is imperatively enjoined. Our concern must chiefly be with those persons who find it practicable to consult comfort, and a certain degree of taste, in the erection of agricultural buildings. So much of human happiness, on the largest scale of the expression, depends on the prosperity of the husbandman, that an unusual degree of interest attaches to his accommodation. But it is obvious that the mere construction of his own dwelling ought to occupy us very little after what has already been delivered on the subject of cottages, the better kinds of which, it is certain, with the addition of out-houses, &c. may be adapted to every condition of the operative farmer. A higher class, that of the gentleman-farmer, seems to demand, indeed, some peculiar attention; and as the ambition of most persons engaged in the profession of agriculture is to rise to that rank, we can scarcely avoid the introduction of some advice and plans calculated to secure the advantages aspired after.

Of Style.

Substantial importance, and an expression of compactness and security, ought to characterise the farm-house. Beauty it may have, but the affectation of elegance is preposterous. This will be easily understood, when it is considered that even cleanliness is not unusually an excellence of difficult attainment. There is something in reality peculiarly disgusting in the frippery and nonsense with which many persons in this profession, of little taste and less judgment, attempt the imitation of their betters. But the spirit that leads a farmer to equal, if not to surpass his landlord, in the appearance of his house and grounds, justly subjects him to a high penalty, the depreciation of his good sense.

The situation is a matter of extreme consequence; regard must be had to a variety of circumstances in fixing it, as the size and form of the lands, the nature of the farm, whether arable or grazing, or both, the position of woods and rivers, the existence of hills or valleys, the direction of roads, &c. &c. These require the nicest consideration, and, in difficult cases, the employment of very intelligent and experienced men. The house, in general, ought to have an unembarrassed prospect, commanding as much as possible of the country. For the same reason, the stack-yard requires to be placed so as not to interrupt the view, and eminences of every kind are to be subjected to the supreme controul. Low shrubberies are quite allowable, but plantations of trees, lawns studded with lofty elms, &c. are at variance with the fundamental principle; much more so are conspicuous hot-houses, elevated dove-cots, and presumptuous summer-houses. These belong to a higher, but, in fact, less important architecture. The size and nature of the family will point out the most essential distribution and magnitude of the rooms. Commonly, it is believed, provided the situation be a lofty one, and the foundation be circumspectly laid, it will be found most convenient to have all the house on one flat. But a room or two above, for occasional retirement and strangers, may be in the list of desireable objects. Best and common parlour, lodging-rooms, kitchen, pantry, and store-room, complete the necessary *morale* of the house itself; dairy, brew-house, &c. &c. which are no less essential, are parts of the outward distribution. The common sitting-room is to be considered, in some degree, in the light of a sentry-box, having a command of all the premises. To perform this office the better, a pretty large and rather projecting window is an advantage. A farmer, like a prudent general in an enemy's country, will always have his eyes in his head, as the proverb goes, and a spy-glass is not a superfluous companion of either! In a single house, this room may occupy an entire breadth; being necessarily, therefore, of considerable size, it admits of all the petty conveniencies of presses, recesses, &c. essential for common purposes. A double house must be so laid out, in reference to the plan of the whole concern, that easy inspection of what is important may be attained. Where there are wings to a house, and the use of them is often expedient, we accomplish the same end, as in the first case, by devoting one of them to the family sitting-room. In our judgment, regularity of plan, however pleasing, is the very reverse of being most conducive to the object of a farm-house; and, besides, when we consider that it is discoverable from *one* point only, we think very little is lost by sacrificing it, even if no other arrangement secured pleasing effect, which is very far indeed from being the truth.

Of Style.

A farm-yard ought to have an easy access from the roads, be well sheltered, plentifully supplied with water, stand somewhat elevated, and present a sufficient extent of surface for commodious outlay. The ground intended for it should be levelled, and, if requisite, be supplied with chalk or clay, in order to prevent the absorption of moisture, so necessary for the due preparation of manure. The buildings ought to be above the level of the bottom, so as to admit of sufficient drains towards the receptacle of the litter. The out-houses most connected with domestic concerns are to be placed nearest the dwelling, and, in general, the distinct branches of the whole economy ought to have corresponding separations, in order to prevent confusion.

To Middleton's Views for Farm-houses, &c. Lond. 1795, Lugar's Country Gentleman's Architect, Lond. 1807, and other works of professional men, we must refer our readers for a variety of specific plans. The last publication, just now mentioned, has some judicious remarks on the subjects of Dairies, Barns, Dog-kennels, Poultry-yard, Piggeries, Malting-house, Brew-house, &c. The first volume of the Communications to the Board of Agriculture may be advantageously consulted for observations on farm-buildings.

SECT. III. *Of the Villa.*

Here we abandon ourselves entirely to fancy and the thousand conceits which caprice and affluence may suggest. The villa is a gentleman's house. Let him submit himself to no law but that of his ability, profess regard to no authority but his own taste in its creation. To say that he ought to do this or that, to adopt the Grecian or Roman model, entomb himself in a Gothic abbey, set the world at defiance by towers and moats and castellated walls, or court adoration in a Mahommedan mosque, would be regarded as idle officiousness. The villa may be in any style of architecture. It may emulate the splendour of the palace, condescend to the lowly cottage, or wanton in every irregularity of design and object. It remains to be said, whether in doing one or other it be beautiful, romantic, or deformed, and in what degree it is so.

In the first place, then, a mansion that receives no embellishment from the surrounding scenery, often claims more exclusive applause than it is entitled to. A distinction ought to be made between a country house and a town house; but the former appellation is quite misapplied if it present nothing but stone and glass to notice. We wish to contemplate nature, wild or improved,—the sloping hill and variegated lawn,—the poetry, if not the sublimity of wood and water.

Secondly, The style of this building ought to correspond with the situation. The venerable Gothic is ridiculed by adjoining gaiety—a castle is sunk to insignificance when planted in a valley,—perfect regularity of architecture, especially if highly ornamented, upbraids the careless freedom of nature seen in her wildest forms,—in short, a degree of suitableness between style and situation is essential to harmonious effect. Even the circumstance of relative distance from a large town, or the peculiarity of the country, on the large scale, insinuates itself at last into our conceptions of this quality. We do not look for a *new* fortress within a mile or two of London, nor for a *Roman* palace in the Highlands of Scotland. It is vain to answer, that this is an arbitrary mode of judging, founded on prejudice and not on reason. Be it so. But what, we ask, has reason to do with a thousand other impressions which external objects make upon us? The fact is, we are so and so constituted as to be thus operated on, and all the arguments and demonstrations of an Aristotle would be thrown away in an attempt to alter us. A child or an idiot, perhaps, may be wheedled into wondering applause of any display of grandeur wherever it is found, but a man of sense, although little conversant with a number of edifices, will feel disgust at such misplacement and confusion of ideas.

Thirdly, A villa is destined for the accommodation of a family in a state of comfort allied to elegance. It is not a nunnery, nor a prison, nor a military fortress, nor a menagerie, nor a church. Why then does it claim kindred to them by very striking resemblance? Fashion will have it so. A house cannot be built every day to correspond with its capricious dictates. But the relations of utility, of fitness, expressiveness of design and object, exist for ages. The utmost influence that fashion ought to claim is that of regard to the character of the times in which we live. The days of monastic seclusion, gloomy superstition, and feudal despotism, are gone by,—we are not now to be bewitched with glass angels and marble saints, or horrified with ghost-trodden turrets and enchanted halls.

Lastly, The correspondence of all the parts of the villa with each other, and the general design, indicate chastity of thought and simplicity of plan. This, when the expression itself is agreeable, is an excellence of high value. Not that we enjoin perfect regularity or an undeviating uniformity in the structure of a villa. Formality is here a vice; so that the plan which renders it necessary in order to fine effect, seems to have been intended for a street and not the obliquities and irregularities of nature. But we contend, on the other hand, for a discoverable subjection of every portion of what we know to be artificial to the arrangement and intelligence of mind; and we cannot even behold that mind, either frivolous or given to freaks, without a painful suspicion of insanity. Houses, we know, are costly things, and building occupies many years and much thought; it is miserable to reflect, that the product is often whimsical and trifling. A mixture of different orders, then, we think, implies an erroneous judgment, to say nothing at all about the transgression of rules; and a tenacious adherence to a set form, excites a notion of a narrow taste and a poor imagination.

On the whole, we dislike imitation, whether of the Grecian, Roman, Oriental, castellated, or Gothic architecture; and there is no difficulty in obtaining a suitable individuality of character. A man of genius in his profession will never be a slave; he will study, indeed, the works of others, and avail himself of their experience, profiting as well by their defects as their excellencies; but with an eye and a heart inspired by truth and nature, like the genuine painter or the poet, he will identify his conceptions with the characters of his subject, and embody them in materials destined, like his fame, for immortality.

For views and examples of what has been done, and may be done, we refer to "Plans and Views of Buildings executed in England and Scotland," by R. Lugar, Lond. 1811; "Designs for Villas, &c." by Edmund Aikin, Lond. 1808; "Designs for Elegant Cottages and Small Villas, &c.," by E. Gyfford. Lond. 1806; "Sloane's Plans, &c. of Buildings executed in the counties of Norfolk," &c. &c.

The general reader, who wishes merely for information in the way of amusement, without having any specific object in view, may have recourse to almost any of the works published under the titles of Tours, Excursions, Trips, Road-books, and Directories, &c. &c.

Sect. IV. *Of Grouped Houses.*

By this denomination we mean those assemblages of buildings which constitute the streets, squares, crescents, &c. of villages, towns, and cities. The difference between them and the solitary structures hitherto treated of is both considerable and important. A new character is acquired, or at least a certain sacrifice of freedom is called for, something like that which a savage must make on becoming a member of a civilized community. He submits to restrictions, certainly not very natural, but ultimately instrumental to his welfare, and at all events essential to the public peace. The villa stood peerless in the field, owning only the superiority of the neighbouring hill and the canopy of heaven; even the cottage had an air of independence which it shared with the friendly thicket, or which enabled it to afford protection to the jessamine, the rose, or woodbine that grew around it. But in the town, redundancies must be lopped off, irregularities confined, order and method studied, every thing must be regimented, schooled, and trained by the precepts of law and the compliances of courtesy. Individual taste and inclination yield to the demands of general convenience. Certain private decorations, or supposed elegancies, notwithstanding, are usually allowed, and ought, indeed, as much as possible to be so, because the prevalent vice of a town in respect of taste is monotony, which is seldom enough broken or counteracted either by this indulgence or the occasional appearance of large and special edifices. There is a very striking difference, in this particular, between ancient towns and those erected since the establishment of regular police and good government. The former seem to have been the product of accidental meetings of cottages, and villas, and castles, and have the interest, therefore, of variety and chance; the latter, on the contrary, are evidently the result of preconceived combinations and adjusted designs, indicative of well-directed intelligence, no doubt, and possessing superior advantages, but at the same time wearisome as the method of a Dutch garden, and totally opposed to every romantic idea. A single city will sometimes afford a complete illustration of this remark, and the case of the Old and the New Town of Edinburgh, to go no farther, is quite in point. An observer, standing on the south-west side of the Calton Hill, which commands both, is instantaneously impressed with a conviction of the happy order and useful arrangement of the modern streets; but a dissatisfied feeling follows, the natural effect of so much stiffness and formality. All the portions of which they are constituted are so extremely alike, that not one has had ambition or pride enough to surpass its republican fellows. In short, the whole is utterly destitute of the expression of grandeur and bold enterprise. On the other hand, the Old Town is at first sight positively offensive by its appearance of confusion and inextricable disorder. But the mind is soon hurried off from this impression, to contemplate, with a kind of poetic ardour and delight, those endless projections, heights, and precipices, by which the hand of man seems to have rivalled the sublime works of nature in their neighbourhood. No where else, we believe, shall we find such confronting extremes. We regret, we must add, that the contrast has been pushed so far, and that a subject, of almost unexampled capabilities, has been so tamely treated. But some relief may be effected by the judicious outlay of the intermediate space; an object of no less consequence than the stupendous embellishment now executing.

Every town ought to contain all those conveniencies which a large society requires; its wells, markets, and places of resort for universal concerns, &c. &c. Health and cleanliness, so difficultly preserved among great masses of mankind, ought to be an object of legislative interference, much more, we have no hesitation in saying, than the opinions and creeds of the people. For these purposes, certain situations are to be preferred, as favoured by climate, soil, exposure, and accidental advantages. For the same reason, the streets ought to be wide; nuisances must be provided for by proper covered drains, and every facility and encouragement given to study neatness and elegance of aspect: A wise and benevolent government would even go farther; and by the politic establishment of promenades, and places of exercise and amusement, either free of entrance, or accessible by moderate means, would cultivate the salutary recreation of both mind and body. No one can witness the squalid, dejected countenances of the lower order of people in large towns, especially in manufacturing towns, without being convinced that there is a lamentable neglect of their highest temporal interests. A century hence, we venture to foretel, unless some extraordinary change take place, the population of Britain, tending, as it does, with portentous rapidity, to eke out the misery of large towns for the greater convenience of trade, will be unable to raise a body of warriors fit to emulate the hardihood and deeds of their forefathers. The observations of Sir James Macgregor on the Medical History of the Peninsular War, fully warrant such an opinion.

Long streets are to be frequently broken for the greater facility of intercourse. Diagonal crosses are more expeditious than right angled. Squares and crescents not only give elegance, but also promote free exposure. Very high houses are troublesome, and preclude sufficient attention to cleanliness. Streets ought to be well furnished with flagged footpaths, having an inclination outwards to the gutter, to permit rain to flow off expeditiously. The particular style of building for the private houses we hold to be a matter of complete indifference, provided they be well supplied with windows of a large size, have a lively appearance, and admit of tasteful decorations.

Sect. V. *Of Public Buildings.*

Public edifices, in a great degree, determine the character and condition of nations. The general concerns of communities require larger places of resort than what are used as dwellings by private persons. Religion, education, amusement, political establishments, and many other institutions, such as no civilized country is altogether destitute of, are of universal interest, and bring large masses of mankind together. Even those constitutions which are most opposed to the liberty of the people, permit and in fact enjoin occasional assemblies as conducive to the ends of government. In the nature, number, and appearance of the edifices, where they occur, we may generally discover a good deal of their history, and of their most striking moral and political features. The style of architecture adopted in them, whether original or derivative, testifies something of their former state and the advancement they have made in the arts of civilization; whilst their present features have invariably an influence on their efforts in this art, and not unusually impress very peculiar marks on its more considerable productions. It is certainly the study of nations, no less than of indiduals, more especially those which encourage intercourse with other people, to procure and maintain respect by the display of what are esteemed symptoms of prosperity. As an indication, at least in the case of states not tributary, this display may more frequently exceed the reality than be below it. But the pride, or good policy in the one case, and the affected humility or sincere parsimony in the other, are equally traits of character to which a well informed observer will give due attention in forming his estimate. The writers on political economy have not been sufficiently studious of this department of statistics.

But though the objects of public buildings, and the means for erecting them, be national, or concern communities of mankind; and though generally there is a certain style of architecture more prevalent in a country than another; yet, on the whole, it is the taste of a few individuals that modifies the existing art. There is indeed a re-action between the conduct of these individuals and some pretty well established prejudices, so that they rarely can accomplish their entire inclination, and thus the public are tolerably well secured against any considerable revolutions. Changes of style, in fact, are neither frequent nor speedy. We have evidences of this in the similarity of many edifices which have

Of Style.

been erected at very distant periods of time. Associations, it would appear, are formed in the minds of most people, which it is unsafe, if not impracticable, to dissolve. Nothing, indeed, can justify the attempt but reasons of expediency so obviously or so easily discovered, and of such a degree of urgency as cannot fail to carry conviction to ordinary minds. Capricious innovations are surely as much to be condemned as the obstinacy that resists their establishment; and if all other circumstances be alike, a preference is due to those models which have been sanctioned by public esteem. At all events, a difference in the circumstances ought to be as considerable as the amount of deviation that is hazarded. Neglect of this precaution occasions much of the dissatisfaction which is expressed against certain kinds of edifices. Generally speaking, there is prudence in conformity, although originality be essential to excellence. But there are a thousand stations between a complete copy and extravagant singularity which ordinary artists may commendably fill up with their productions.

Few errors, perhaps, would be committed, and undoubtedly few important alterations in style would be projected, were a metaphysical conceit got rid of which we have already endeavoured to expose, viz. that some forms and proportions are naturally more beautiful than others. Were they to abandon this mischievous absurdity, artists would almost certainly avoid the evils of affectation, and at the same time secure for their works the beneficial operation of those principles of judgment on which the decisions of taste are founded. It is of consequence for them also to remember, that no combination of the materials on which they work can ever express any of those pasions of the mind that are the objects of sympathy, and the source of the interest we take in the history and actions of our fellow creatures. In this respect, architecture is inferior to painting and sculpture, confined as they are to indicate the signs only of these passions, and to delineate the momentarily co-existent assemblage of events to which they give rise. But, perhaps, within its range of expression, it equals those arts in the amount though not the quality of effect on the feelings. That mind certainly is extremely dull, if not defective in a faculty, as many are with respect to musical ear, which is not susceptible of peculiarly strong emotions on the contemplation of its nobler monuments, independent altogether of regard to the ultimate ends for which they were intended.

The emotions thus produced are not always the same, but differ in different cases, according to the associating principles brought into action; and hence they furnish us with some means for pointing out the nature of buildings, and at the same time of heightening the effect which the consideration of that nature, when pointed out, is calculated to produce. These principles, then, being once established, become as powerful on the mind as if the forms, proportions, and appearances with which they are connected, or which tend to excite them, were naturally and essentially expressive, as has generally been imagined. It is this apparent concurrence with a matter of fact, accordingly, that has given the theoretical opinion now alluded to its most specious claims. But there are not wanting other instances of the partial accommodation of an erroneous hypothesis to the phenomena of nature. Is there one, indeed, among the thousand false notions which domineer over the mass of mankind, that could maintain its place in their esteem without some such recommendation? But it is not enough to entitle a theory to the honours of a law of nature, that it affords a satisfactory explanation of many facts; the principles on which it is built must be shewn to have an actual existence. In the present case, there arises a decisive objection, from the circumstance of a more general principle than what is assumed by this theory, one, too, of whose reality we have the highest convictions of experience, requiring no such aid to account for all the facts in question.

It is the business of the artist, then, to ascertain the peculiar associations which take place in various cases. He must have recourse to experience, distrusting altogether the pretensions of rival systems; and the results of his own unbiassed examination ought to be as imperative on his practice, as any deductions from a theory which might even possess the authority of a law of nature. The more extensive his observation has been, and the more scrupulous his caution to discriminate between associations that are of universal occurrence, and those which are the product of accidental and rare combinations, the greater is the probability that he will avoid narrow prejudices, and accomplish the higher destinies of his art. If the advantage of travelling be denied him, and of course the benefit of personal inspection, he must endeavour to remedy the deficiency by the liberal study of the best descriptions of public edifices in different countries and styles, taking care to form his taste on the general conceptions which arise in his mind rather than the more intimate acquaintance he may possess with particular examples of excellence. What but some paltry notions allowed to spring up in the mind during the neglect of this corrective discipline, and that inveterate propensity in unpractised reasoners to draw general conclusions from particular premises, could give rise to the empirical dogmatism and ostentatious trumpery practised in this profession? It is lamentable, that the very censure which is occasionally bestowed on the more absurd of these vices, commonly proceeds on a principle which recognises the sacredness of the parent delusion. The taste of the artist, indeed, is condemned; but this being supposed entirely a *voluntary* principle, his deficiencies of information and judgment escape detection, though, in reality, the *necessary* source of his errors. Taste, properly speaking, is little concerned in the matter. The artists too often employed are mere jobbers, who have not had time, inclination, or talent to cultivate what is deserving the name of that faculty; and those who employ them are often too ignorant to suspect that what is offered to their admiration is an absurdity. The evil, which is abundantly important to excite solicitude, requires a double remedy. In the first place, the public mind must be rectified as to the objects and capabilities of architecture; and, 2dly, men intended for the profession ought to undergo a

Of Style.

regular and scientific education. Is it not desirable for both purposes, but peculiarly for the latter, that our universities had endowments for teachers of this most useful art, and that attendance on their instructions for a certain time, and an acquaintance with several subsidiary branches of knowledge, were enjoined on all those who aspired to the honours and emoluments of its practice?

In considering the characters of public buildings, three questions present themselves. 1. Is it possible, or necessary, to suggest the nature or object of such buildings by visible signs? 2. Does the art of architecture afford such signs? 3. What are the species or kinds of architecture peculiarly suitable to the intended manifestations? These three questions might all be resolved into one, viz. What are the emotions actually excited in the mind by the productions of this art? But it will be found most advantageous for the student to investigate the topics separately.

The first question involves two particulars, the practicability and the expediency of intimating design. As to the former, we may remark, that from the earliest ages it has been imagined not only possible but even easy, to express affections of mind by the forms and qualities of matter. The arts of the statuary and painter, considered as distinct from the mere imitation of things, proceed upon this supposition; and accordingly we find, that the ancient professors of both arts often busied themselves in figurative or emblematical representations of ideal objects. In course of time these figures became as generally significant and well known as the correct delineations of individual persons. There are familiar examples in the emblems of justice, plenty, faith, hope, &c. &c. handed down to us, with little alteration, from very early times. But these instances are far from deciding the present question, though they seem to indicate the universality of the opinion, that abstract qualities may be signified by visible forms. It is evident, that, even admitting the correctness of such forms considered as signs, it still remains to be determined whether or not the intention, or object, of buildings bear a resemblance to the qualities thus indicated. Here it would be requisite to enquire, therefore, into the variety of ends contemplated, or, in other words, to specify the kinds of edifices. A list of these would present many diversities, allotted to the distinct purposes of civilized societies. Then the question would be, how far do any or all of these correspond with such mental qualities as have been alluded to? Perhaps the utmost licence which could result from the inquiry is, that each of these diversities having a close affinity with one or other of the ideal beings, may, therefore, be designated by its respective emblem. Thus, for example, the mere intention, motive, or object, which prompted to the erection of a church, hospital, or court of law, might be represented by figures significant of piety, health, or justice. But, in all this process, it is evident, we have not got beyond the arts of sculpture and engraving; and hitherto not a hint is suggested which could be of the slightest utility to the architect. Though it appears, therefore, impracticable to suggest the nature of a building by any sign expressive of the intention which led to it, yet there is every reason to believe that when that nature is by any means discovered, then there may immediately arise a conviction of its suitableness. Accordingly, the appearances which excite this conviction are not unfrequently conceived to be expressive of nature itself; and, in reality, it will be found that the expediency, or necessity, of signifying this nature, is resolvable into the propriety, or advantage, of exciting such a conviction. This is the origin of the doctrine of fitness, as it is called, to which some incautious reasoners have referred the pleasurable emotions arising from some of the productions of the art. There is still another source of error, to which it is necessary to advert before proceeding to discuss the second question. It is the confounding together the end or object of a building and the emotion which that end is fitted to excite. For the former, it now appears there is no significant expression in the art; in other words, the productions of the art do not directly suggest the purposes for which they are intended. But the latter, it is certain, may be, and often is excited, naturally or conventionally, by the building itself. This is an important distinction, and at once conducts us to the legitimate aims of the art, by pointing out the peculiar expression of which it is capable.

We are now furnished with a qualified answer to the second question. Architecture does not supply signs from which we can directly infer the ends, or purposes, of its productions, but it is capable of exciting some, at least, of the many emotions which these purposes or ends, when accomplished, occasion in the mind. Hence, then, from the emotions we may judge of the purposes. It now becomes an interesting inquiry, what are the emotions which it excites? And from this again necessarily results the determination of practice in every case of consequence. The emotions are numerous, as may easily be ascertained by experiment, or by perusing almost any of the works which treat of architecture as a fine art. We have given our reasons already for preferring the enumeration and arrangement which Mr Alison has adopted, without being perfectly satisfied that he has quite exhausted the subject, or taken into account every circumstance which is likely to influence it. The attention of the artist is peculiarly demanded here, because in no exercise of his profession is he so liable to gross error as in fixing on the kinds and degrees of emotion which are to be excited. He must know the precise capabilities of the art, in the first place; beyond these he cannot take a step without certainty of failure. The kind, again, is pointed out by the object or purpose in view; and the degree is limited by the fund on which he operates, and the peculiar circumstances of the case. Lastly, he must be cautious not to attempt the production of contrary, or too many emotions. Perhaps every instance of considerable error may be referred to a neglect of one of these simple rules; and, on the contrary, a certain degree of success must be the infallible result of attending to them.

The last question which has been stated, can only be solved properly by the results of experience.

Of some of these it is necessary to speak. The effects of architecture are of two kinds, those which immediately spring up in the mind on the contemplation of the objects, and those which take place through the medium of the principle denominated the association of ideas. One building may produce both in the same individual; and, in general, the effects which do occur, are determined as much by the peculiarities of the spectator's character, as by the nature of the building presented to his notice. Hence the difference between the judgments pronounced by the vulgar and the man of cultivated taste, both equally sincere expressions, it may be, of the real effects which are experienced. It is clear then, that, in determining this question, we must condescend on the individuals, or characters of the persons who are to decide, else the answers would be various, and in reality contradictory. How absurd, therefore, is dogmatism in this case, and how endless the controversies which are frequently agitated on the merits of different kinds of buildings! But let us not carry this observation too far. It must be restricted to the second sort of effects, for as to the first, it may be easily made to appear that there can be little or no disagreement of feeling.

Every distinct quality, we apprehend, is productive instantaneously of a distinct emotion in all the individuals who observe it. But it is not obviously true, that every emotion admits of being distinctly stated in language. The fact is, that few persons so far discriminate between their emotions, as to be able to present them in any creditable form to their understandings. Some general terms are usually employed to denote the larger differences of classes of emotions, and hence we speak of agreeable and disagreeable, certainly the most universal of such terms,—or of gay and melancholy, lively, dull, &c. &c. But the minuter shades of difference escape detection, perhaps because of the merely momentary existence they have in the mind, or from a habit of inconsidertion as to what passes there, of which every person must be sensible, when not roused by some powerful motive. Now, were there no other principle to operate, buildings of very different characters might produce emotions so much resembling each other as scarcely to admit of distinction, at least in common language. This is actually the case with the generality of people, who will be found to express themselves alike respecting very dissimilar examples. It is evident, then, that their praise would afford little satisfaction to an artist; and hence he is induced to seek the approbation of persons who, besides their agreement in the common emotions, are likely, by their education and studies, or the natural susceptibility of their minds, to experience the secondary but higher effects which his art can produce. This is certainly an appeal from the many to the few, and having been often practised has at last constituted a tribunal of taste, whose decisions are almost irreversible, and before which every intelligent artist is anxious to bring his productions. It is fortunate for the credit of this tribunal, that all its decrees *may* be perfectly, and now perhaps generally are, reconcileable with the sentiments and conclusions of the unlearned. There is every reason, therefore, for preferring its reply to the question before us; and hence, it is absolutely incumbent on the student to familiarize his mind to all the varieties and degrees of emotions, primary and secondary, occasioned by the different styles. The former he may easily ascertain by attending to his own sensations; the latter must be learnt from frequent and careful comparison of the criticisms and observations on the most remarkable specimens of the art, which abound in many well-known publications.

History of Architecture.

Origin.—It is vain to seek for the origin of this art among any particular people, the necessity for it, and the genius required in its cultivation, being as universal and as various as the materials on which it operates. It has been practised, we know, in every country, and in all ages, favoured with the benefits of civilization. The savage life itself is rarely destitute of some artificial defence against the violence of the elements and the ferocity of wild beasts; and those contentions in which rival tribes so frequently engage, have furnished powerful motives towards its invention and exercise.

We have an illustration of this last remark in the Hippahs or Heppahs of New Zealand, described by Captain Cook. The incessant hostilities of the natives of that country have converted their villages into forts. Speaking of one of them, that navigator says, "the best engineer in Europe could not have chosen a situation better adapted to enable a small number to defend themselves against a greater;" and, considering the imperfection of their tools, the structures themselves, according to his description, must be allowed to display great judgment and ingenuity. In the accounts of the voyages performed by this very intelligent officer, we are occasionally supplied with curious information respecting various degrees and kinds of primitive architecture. Even the miserable huts of Easter island, one of the most forlorn and unfortunate of the islands he visited, manifest skill, though vastly inferior to that of the Otaheitans and other people. They are "constructed by setting sticks upright in the ground, at six or eight feet distance, then bending them towards each other, and tying them together at the top, forming thereby a kind of Gothic arch. The longest sticks are placed in the middle, and shorter ones each way, and a less distance asunder, by which means the building is highest and broadest in the middle, and lower and narrower towards each end. To these are tied others horizontally, and the whole is thatched over with leaves of sugar-cane. The door-way is in the middle of one side, formed like a porch, and so low and narrow, as just to admit a man to enter upon all fours." The largest house seen here by Captain Cook was about 60 feet long, eight or nine feet high in the middle, and three or four at each end; its breadth at these parts being nearly equal to its height. It is very singular, that this island, so remarkable for some gigantic figures of stone, contained also certain buildings of the same material. We are indebted to Mr George Forster, who accompanied Cook in his second voyage, for some particulars respecting them, History. which the reader will find in Kerr's Collection of Voyages, &c. vol. 14. p. 272. It is in such conditions of mankind as have been discovered by modern travellers and navigators, that we are provided with an unanswerable objection to those claims for the supposed honour of giving rise to this art which have been advanced by fanciful writers in behalf of different nations. Architecture, they seem to prove, is the creature of circumstances that are by no means confined to any period or region of the world.

The instances of contrivance and skill now alluded to, render probable the historical relations that have come down to our times, respecting the prevalence and extent of this art among the earlier generations of mankind. Admitting that these possessed an equal share of intelligence with modern savages, it is surely fair to imagine that they were at least equally successful in cultivating so important an art. But there are not wanting reasons for the opinion, that the exertions of some of them could scarcely fail to be much more considerable. At all events, the essential advantage of that long space of time which they continued, must have occasioned a decided superiority on the part of those people who had earliest arrived at civilization. This probably has originated and strengthened the notion, that some particular nation invented the art, though completely at variance with every distinct example of underived national style. Priority of invention and employment may be conceded to the Egyptians and some of the eastern people, without robbing others of the merit of originality.

Early condition.—We are chiefly concerned with the state of architecture in Egypt, the country from which the Greeks, to whom the western world is indebted for its first acquaintance with the fine arts, derived their instructions. This, then, may be considered, without any determination of a question which has often agitated antiquaries,—viz. whether Egypt or one of the eastern countries was the parent of the art. It is sufficient for us to observe with respect to this discussion, that Egypt, Phœnicia, Chaldæa, India, and China, may be proved, on respectable authorities, to have made considerable advancement in architecture in very early times; but that it is extremely difficult, if not impossible, to ascertain which of them was soonest engaged in it.

The immediate descendents of Noah, it is probable, retained some of the knowledge of the Antediluvian generations, which might serve as the basis of the art practised by them as long as they continued united together, and for some time after their separation at the plain of Shinar. We learn from the Mosaic account, certainly the most authentic history of this period of the world, that several cities had been built prior to the undertaking at Babel, which occasioned that event. Their names are given in Genesis, x. 10. &c.; but no information is afforded respecting their extent, or the materials of which they were formed. Stone, we may almost positively declare not to have been used. The cities of the plain, we may add, whose lamentable overthrow could not be averted by the intercession of Abraham, consisted of combustible materials, which we know were generally used in the architecture of ancient times. History.

Egypt, it appears, however, never abounded in wood; and accordingly its inhabitants had recourse to bricks formed of a kind of mud or clay, held together by means of straw, and hardened by exposure to the sun and air. There is ground to believe also, that they very early employed stone for the same purpose; and the art of dressing it has, with some propriety, been ascribed to them. Their ingenuity and science were soon distinguished among the neighbouring nations; and it is mentioned to the credit of the Jewish lawgiver, in after times, (Acts vii. 22.,) that he "was learned in all their wisdom." President Goguet, who has treated the subject we are now upon with his usual discrimination and industry, is of opinion, that some of the embellishments of the tabernacle erected by Moses in the wilderness had been previously adopted by them. "I believe really," says this sensible writer, "that there must have been some relation between the Egyptian temples and the tabernacle. It is true, strictly speaking, this work ought not to be looked upon as a piece of architecture; it was only, to speak properly, a vast tent; this is the first idea it offers to the mind; but, by reflecting on it more attentively, we shall perceive that the tabernacle had a great relation with architecture. We ought to look upon it as a representation of the temples and palaces of the east. The whole construction presented the model of an edifice, regular, and distributed with much skill." Its columns, surmounted with chapiters, give us an idea of the essential part of an architectural order. Viewed in this light, as a monument of the existing taste, we cannot help thinking that architecture had already got far beyond the state in which it merely yielded shelter from the weather, and had assumed an important rank as a fine art.

Among the Egyptians.—To the reign of Sesostris is ascribed the principal part of those buildings, whether intended for utility only or embellishment, which rendered Egypt so conspicuous in the list of kingdoms. But it is impossible exactly to ascertain the time in which this remarkable personage existed, and many of the relations concerning him appear unworthy of credit.

Thebes, the capital of Egypt, is immortalized in the poems of Homer, as the richest and most populous city in the world, so early as the time of the Trojan war. If there were not reasons for believing that the bard judged of it by comparison with the still inconsiderable cities of Asia Minor and Greece, and indulged his fancy in the description he gives of it, we might be induced to assign it the highest place among the wonders of ancient art. The concurrent voice of other authors seems to demand this as a right; but there is always room to suspect the existence of a disposition towards the marvellous in their representations, and that they were more anxious to improve on previous reports, than careful to ascertain their accuracy. No greater evidence of this remark, perhaps, will be asked for than the assertion of Pomponius Mela, that this city contained within its walls a million of warriors; whereas Herodotus reckons only forty-one thousand in all Egypt! But allowing for exaggerations, sufficient truth remains to call forth admiration. The ruins of this famous city, which have frequently been visited by modern travellers, testify an extent and magnificence to which there are not many parallels in past or present times. But it ought not to be forgotten, that these ruins are the mingled product of the original city and the subsequent productions of Grecian and Roman power, which successively triumphed in this celebrated region. A very minute and skilful examination would be requisite to determine the respective shares of each; and this adjustment is the more difficult, because it is probable that both the latter partook a good deal of the Egyptian taste and manner. Those who wish to be informed as to what has been done in this way, will find enough to gratify their curiosity in the travels of Pococke, Norden, and Denon, not to mention others spoken of in Goguet's work. The account which Mr Hamilton has given of the ancient and modern state of Egypt, may also be profitably consulted.

Thebes deserves to be called the city of temples, so many remains of these buildings being discoverable in its ruins, and some of them indicating, by their size and appearance, the immense consequence that had been attached to religion. The reflections of Denon on this circumstance are worthy of notice, and are well borne out by the observations of other writers: "Still temples, nothing but temples! and not a vestige of the hundred gates so celebrated in history, (especially by Homer); no walls, quays, bridges, baths, or theatres; not a single edifice of public utility or convenience; notwithstanding all the pains which I took in the research, I could find nothing but temples, walls covered with obscure emblems and hieroglyphics, which attested the ascendency of the priesthood, who still seemed to reign over these mighty ruins, and whose empire constantly haunted my imagination."

Of Memphis, the second capital of Egypt, built several centuries after Thebes, not a vestige remains to mark the spot where it stood. But in the vicinity of the place assigned to it, not far from Cairo, on the opposite side of the Nile, are found those stupendous structures the pyramids. It is worthy of notice that Homer never makes mention of these singular edifices, nor of the name of Memphis. This is most probably accounted for on the supposition, that neither the one nor the other existed in his time. The descriptions of the pyramids of Egypt, of the famous labyrinth near the lake Mœris, and of various other remarkable structures, belong to another department. There were many more cities in this region, of which mention is made in different classical authors, but it is unnecessary to specify them in this place. Alexandria, founded by the Macedonian conqueror, and in great measure made up from the ruins of Thebes, cannot be considered as belonging to this period, or in any degree illustrating the history of Egyptian architecture, as it was built by a Grecian, and in the Greek taste.

From all that can be collected in ancient authors, and in the reports of those travellers who have visited this country, it will not be difficult to form an opinion of the state of this art as practised by the Egyptians. Their notion of perfection in buildings corresponded exactly with that of a certain people we have somewhere read of, as to beauty in women. Bulk is the main thing aimed at. In endeavouring to accomplish this, the nature of their materials, and their ignorance of scientific principles, forced them to adopt the simplest and least hazardous forms. Immensity of dimension required enormous strength, and occasioned a durability to which perhaps nothing but wilful aggression could set limits. Cambyses signalized his mad invasion of Egypt by this ungenerous device. Subsequent conquerors followed his example. But enough remains to point out its nature and principal features. These may produce an emotion of awe somewhat allied to sublimity, but are altogether destructive of pleasurable ideas. In the Egyptian edifices, in short, all is cumbrous, inelegant, and clumsy; and the very ornaments are calculated to disgust a mind that had ever been gratified with the insinuating graces of a purer model.

The Egyptians, it is demonstrable from their works, knew nothing of the nature of an arch, and appear not to have used timber in their larger edifices. These circumstances account for much of what is objectionable in their building, particularly the constant adoption of flat roofs, often of great size, and consisting perhaps of no more than one piece of stone, and the multiplication of huge columns, necessary indeed for support, but productive of an embarrassed and heavy appearance. The hasty assertion of M. Dutens, in a work published several years ago, (*Recherches sur le Tems le plus reculé de l'Usage des Voutes ches les Anciens,*) in which he has attempted to carry back the discovery of the arch to a very early period, viz. that there are examples of it to be met with in the remains of Egyptian architecture, is easily explained by a circumstance which he appears to have neglected to consider. We mean the introduction of both Grecian and Roman science into that country long after the times in which its inhabitants could boast of independence. There is an excellent *critique* on this work in the Edinburgh Review for January 1806, where the fanciful opinions of the author, and his gross errors, are exposed beyond the possibility of defence. In so far as Egypt is concerned, Goguet had successfully anticipated and replied to the question. See the translation of his admirable work on the Origin of Laws, &c. printed at Edinburgh, 1761, vol. 3.

In the east.—Before proceeding to notice the state of architecture in Greece, it will be proper to make a few observations on some of the cities of the east.

That part of Asia which is denominated, from the peculiarity of its situation, Mesopotamia, has been pretty generally fixed on as the original seat of civilization, and, indeed, of mankind. However this be, certain it is that some of the most ancient and largest cities in the world were built in or near it. Of these, Nineveh on the Tigris, and Babylon on the Euphrates, have attracted the greatest attention. We have ample accounts of both from sacred and profane writers. These will be elsewhere considered; we have merely to mention at present the probability of their resembling each other in size and appearance, and that there are now no traces of their existence to be met with, from which we could form the faintest conception of their style and magnificence. The vestiges in the site of the latter remaining in the fourth century cannot be supposed more ancient than the attempts, very feeble ones it must be allowed, made by Alexander, and some of his successors, to restore its former glory. After the ruin of the Assyrian empire, the Persian monarchs generally resided in Susan, Ecbatana, and Persepolis. The ruins of the palace in the last named city, imagined to be the same that was destroyed by Alexander, have been particularly described by Le Brun, and are occasionally noticed by later travellers. Seleucia, (the modern Bagdad,) Heliopolis, or Balbec, Palmyra, or Thadmor, &c. &c. are to be ascribed to the Greeks and Romans, and do not, therefore, properly speaking, belong to this part of our subject. It is unnecessary for the object we have in view to make mention of the cities of India, China, &c. We turn, therefore, to the history of architecture, as descending to the western world, through the purifying channel of Greece.

Among the Greeks.—The progress of the Greeks from obscurity to the highest fame, is one of the most inviting events in the history of mankind. Their poor beginnings in a small territory, always liable to be overwhelmed by their neighbours, could afford no promise of the dignity to which they afterwards attained. It is not easy to assign very satisfactory reasons for the rapidity of their rise. Political circumstances, perpetual jealousies the almost infallible attendants on minute divisions of the same region, and perhaps, in some degree, the physical peculiarities of their country, all come in for a share in the effect; nor ought we to forget the advantages which they derived from occasional intercourse with people more advanced in civilization. The greatest men in ancient Greece accomplished themselves in useful learning during their travels and residence in foreign countries. Architecture is one of the arts for which, beyond the erection of the merest hovels, they seem to have been indebted to Egypt and Asia. But it was their ingenuity and good taste which elevated it to the rank it now holds, and which still predominate in it wherever it has been liberally cultivated.

We shall pass slightly over the state of architecture in the earlier ages of their history, as too obscurely mentioned by the ancients to yield satisfaction, and too insignificant to warrant much inquiry. Their first buildings were composed of wood, with which some parts of Greece abounded. The piety of the people gave rise to temples, though for long of very mean structure and appearance. The temple of Delphos, for example, afterwards so famous, was originally no more than a thatched building, covered with laurel branches.

Cadmus is supposed to have introduced the use of stone into Greece, as a substitute for wood. The cities of Argos and Eleusis are understood to have been founded by the first sovereigns of this country. Throughout the whole of what have been called the heroic ages, architecture was imperfectly practised, and had not risen to any dignity as a fine art. Great attention was paid, indeed, to the decoration of the inside of houses, but the rules for proportion and the principles of style were not then understood. None of the edifices described by Homer, for instance, give us any idea of ornamental building, nor does this poet seem to have had the slightest conception of an order. He mentions but does not describe the temples of Minerva and Neptune; and his language, in speaking of the columns of certain palaces, implies that they were merely posts of wood. We may confidently affirm, that no very great improvement took place in this art till a considerable time after the Trojan war. The colonies established in Asia Minor, subsequent to that event, are, with much probability, credited with the chief discoveries and embellishments. The former inhabitants of that region had been careful enough to decorate some of their edifices. This may be presumed from Homer's account of the palaces of Priam and Paris, in which he speaks of porticoes and polished stone, but in so vague a manner that it is impossible accurately to find out his meaning. (See Cowper's Homer's Iliad vi. line 277, &c. and Goguet's Remarks on the expressions used by the poet.) The arts of preparing stone for building and sculpture, if not painting and working in metals, were probably derived from the Phœnicians, the most enterprising people in that age of the world. Mechanical knowledge, however, was still very imperfect and confined among the Greeks, from which we may infer the improbability of their having erected any considerable buildings in this early period.

Orders invented.—The Doric and Ionic orders were invented by the Asiatic Greeks, but at what period is not exactly ascertained. Vitruvius, an author much valued for his information on the subject of this art, has placed it too early; for it is inconceivable that Homer and Herodotus, and other writers, should have passed them over unnoticed, if they had been in existence before their time. These orders were no sooner discovered than they were universally adopted. Almost every province in Greece testified its approbation of the first models, and temples and other edifices in imitation of them multiplied with great rapidity. This people, in general, shewed extreme modesty in their private dwellings, reserving the excellencies of their architecture for public purposes. An individual, whatever his riches or power might be, would perhaps have incurred some danger in an attempt to surpass the common neatness and simplicity of his countrymen. Modesty of appearance, indeed, is a virtue which the members of a republic find it a wise policy to cultivate. The influence of this spirit might even be exerted on the style of the public edifices themselves, which certainly secured powerful effect without the aid of minute decorations.

It is questionable if the Corinthian order, which was not invented till some time after the others, were not too gaudy for the sublime conceptions and simple taste of this people during the best part of their history. Certainly it is seldom to be met with in the remains of their edifices erected before the predominance of the Roman power. The fatal consequences of the Macedonian conquest on the independence and politics of Greece, had previously been extended also to their efforts in this art. Their finest and most dignified productions were the offspring of a better spirit than that event could engender. It was late in the progress of this art that the Greeks employed the different orders together in the same building. The chief edifices of antiquity were all in one order. Of the Doric, may be mentioned the temples of Juno at Argos; Jupiter Nemeus between that city and Corinth; Jupiter Olympius at Olympia; Juno and Minerva at Elis; Minerva, (the Parthenon,) at Athens: Juno in the isle of Samos; and Apollo in Delos. The Parthenon built in the time of Pericles, the great promoter of the arts, is esteemed the noblest example. The temples of Diana at Ephesus and Magnesia, those of Æsculapius and Apollo at Athens, of Juno in Attica, and many more, were of the Ionic order. The fine examples of the Corinthian were reserved to signalize the conquests and luxury of the Romans. For particulars respecting the construction of the Greek dwellings and the remains of the nobler edifices, &c., we refer the reader to the Abbe Barthelemi's Travels of Anacharsis; Stuart's Antiquities of Athens; and the work of Vitruvius. The critique in the Edinburgh Review as to the use of the arch among the ancients, formerly alluded to, merits a careful perusal. We entirely agree with the writer, that no unequivocal example of it, as a principle of construction, is to be found in Greece or any of the neighbouring states before the age of Alexander the Great, about which time, and no doubt greatly in consequence of the immense revolutions that had taken place in their political affairs, most important changes in their arts and sciences and taste were effected. But, on the other hand, there is every reason for concluding, that the pointed roof was much earlier employed in their temples and other large edifices, if not for the opinion that it was actually the invention of this ingenious people. M. Dutens, probably, has confounded together this form, or some mere modification of it, with that scientific arrangement of materials on the principle of equilibrium, to which alone the name of arch is properly applied. The roofs constructed by the Egyptians, the Persians, and most other eastern nations, were always flat. How the arch might have been discovered we have elsewhere shewn.

The Romans copy the Greeks.—It is a consolatory thought to a benevolent mind, that the empire of genius is more permanent than that of military power. Unlike the latter, it is not merely tolerated from a conviction of necessity, which every feeling of the heart is disposed to terminate, and which soon or late must vanish before the accumulated energies of human will, but is rooted in the affections and faculties of mankind, and acquires strength from the infant curiosity and awakening zeal of every new generation. Those tyrannies of the ancient world, which so long rioted on liberty and curbed the feeblest effort towards improvement, as hostile to their continuance, could not altogether destroy the natural inclination for change from which that effort proceeded, nor prevent the disclosures of time and casual observation, intended, in the order of Providence, for its encouragement. Even the lamentable conquests over civilization and refinement which so often threatened the extinction of society, and generally injured the monuments of its progress and industry, were occasionally avenged, and their evil counteracted or remedied by a spirit of admiration which seized on the victors, and urged them to imitate, if it did not enable them to surpass, the vanquished in the arts of peace. The stream that had ceased for a time from the rubbish or sand which interrupted its course, or that had sunk out of sight in the convulsions of its channel, was destined to appear again in a fertilising current, made larger by delay, or become more powerful from the very barriers which opposed it. Such was the triumph which the genius of Greece obtained, at the very time when her arms owned the superiority of a rival, and for ever abandoned the contest for independence.

The Romans, whose whole history was a series of aggressions and conflicts, and whose whole moral and physical efficacy as a nation was concentrated in the sword, had never found leisure from their ambition to cultivate those liberal arts which so much enhance the enjoyments of life. But they had sensibility enough to be smitten with their beauties, when presented to them in the course of their conquests, and the candour to accept instructions from a people that excelled in them, when no longer capable of offering resistance to their lust of empire. Victory after victory extended, indeed, the power of these masters of the world, but more and more confirmed also their intellectual devotion; and at last, when there scarcely remained a single field in which they could assert the superiority of their arms, they found themselves completely subdued in mind by the inhabitants of a small part of their dominions, and that, too, by the agency of objects which their original and long boasted ferocity would have spurned as unworthy the regard of their women and children. The character of the warrior was now irretrievably exchanged for that of the student; patriotic self-denial and contemptuous hardihood were lost for ever in the love of indulgence that follows success and the blandishments of prosperity; the supremacy of intellect, in a word, was clearly established on the ruins of the greatest military power which the world had hitherto witnessed.

Roman taste degenerates.—This extraordinary revolution is more to be rejoiced in as a promise of the ultimate attainment of mind in the progress of mankind, than as quite satisfactory in all the circumstances of taste and judgment by which it was accompanied. In so far as architecture was concerned, these must be allowed to have suffered loss in the grosser conceptions, more hastily obtained acquaintance with the art, and over-abundant wealth which characterised the new votaries. The Romans could not content themselves with the dignified simplicity of their models, but sought additional gratification in meretricious ornaments, and an indefinite variety unknown to their masters. Every device which fancy could suggest or money execute, was hazarded in the indulgence of a luxurious disposition, certainly of much more frequent occurrence than the understanding that knows how to appreciate and rest contented within the limits of attainable enjoyment. Augustus boasted that he had changed Rome from brick to marble. Some of his successors appear to have believed there remained for them no source of similar self-complacency, but the rivalling or exceeding him in extent, magnificence, and profusion of buildings. If more costly materials could have been generally obtained, there existed every disposition for their employment. Ambition had now changed its object among the Romans, who became as zealous in decorating the world as their forefathers had been in destroying it. Humanity rejoiced in this conversion, though taste could not always join in applause. The most distant provinces of their vast empire were visited by their grateful enthusiasm; and those splendid remains of the art which still render some of them so interesting, prove at least the boldness of conception, and the immensity of the means, by which this people endeavoured to secure the honours of their name and character with the remotest generations of mankind. It is no doubt impossible, in contemplating these monuments, not to be struck with the debasement of style which had taken place among them, especially in the decline of their glory, or to deny the absurdity and the extravagance in which many private individuals had indulged to the detriment of the art; but justice must allow, that the liberality of their views, where the public good was concerned, and the spirit by which they were actuated to unite elegance with utility, merit the warmest gratitude, though the result fail to excite the highest admiration. Their mistakes, in point of taste, were almost inseparable from the disposition of mind and feeling with which they first devoted themselves to the fine arts, and the circumstances in which they continued to cultivate them. On the whole, too, considering the very generosity which these mistakes display, and the effect it had on the subsequent cultivation of the art, we should not scruple going a step beyond pardon of the Roman architecture, were it not for the strong conviction, that it is the common and almost invincible propensity of ordinary artists to copy gaudy examples, even without the encouragement which approbation of them bestows.

Roman style renewed.—At the distance of some centuries, the Roman style, a modification or rather a corruption of the Grecian, was revived in different countries of Europe. A veneration for classical antiquity, no longer perhaps thought injurious to the prevalent superstition, and newly wakened by the collision of men's minds which literary and commercial intercourse had occasioned, was speedily extended to those noble edifices which had been the delight and the glory, as they now proved the eulogists of departed genius. Italy, as might be expected, was forward in the work of restoration, and long possessed the finest specimens of its power. France was slow in following the example. Greater ardour and more successful enterprise were shewn in England, in which the genius and skill of Inigo Jones, Sir Christopher Wren, Sir John Vanburgh, and many other eminent men, raised up rivals to the splendid productions of Brunelleschi, Palladio, Vignola, &c. noted as the chief of the Italian architects. Their works had certainly the happy effect of fixing the public taste as to some of the larger description of buildings, on a basis that could be defended by recognised principles, and will probably long retard the progress towards the last stage of corruption, mere sceptical licentiousness.

Contest between Classical and Gothic Architecture.—The principal obstacle which for a time resisted the introduction of the Roman style, in some of the European states, was the existence of a very different species of architecture, which shed an almost solitary ray of scientific consequence on the dark ages. It does not appear to have received the name of Gothic till towards its decline, when the ardent patrons of the revived classical taste bestowed on it that opprobrious epithet as likely to accelerate its ruin, and promote the establishment of their own idol. There is even reason for supposing that this name, which so long afterwards proved injurious to it, when there could scarcely remain a wish on the part of any one that it might be further operative, was at first only accidentally applied to one of the meanest branches of the style, or rather indeed to a species of building of too humble a nature to merit any notice, and that it was afterwards invidiously applied to another object, which though of so high pretensions and undoubted merit, had not hitherto been peculiarly designated. It seems utterly impossible that any one, however warm his affection for another style of building, should have ever beheld a good example of the Gothic, and felt an inclination to vilify it. Nor, so far as we know, is this term, as applied to the style in question, ever used in modern times, without a regret that it is so apt to convey an unjust idea.

The Gothic architecture, wherever it arose, or by whomsoever invented, was, at its appearance in Europe, entirely confined to the structure of Christian churches. Certain peculiarities in its origin perhaps, and a wish to differ in appearance from the remains of pagan idolatry, may have occasioned this restriction. The national establishment, then, of Christianity, had probably some connection with so wide a departure from former style; but there is ground for believing that the change had at least commenced some time before the reign of Constantine, though it did not receive the sanction of the Roman people till about that period. Undoubtedly, as we have already noticed, their style had varied much even before this time, and some of their latest edifices, it is demonstrable, exhibited features to which the characteristics of the Gothic architecture, afterwards established, might claim a degree of affinity. Thus, the arch more especially, of which this people had greatly availed themselves, and which had undergone a variety of forms and duties, may be most satisfactorily traced through the whole progress of the art among them, till the developement of the new style.

The intercourse which a profession of the same faith effected between the capital of the western world, and the inhabitants of the countries of Europe, materially directed, and in fact determined the general taste as to ecclesiastical buildings. Vanity, emulation, and devotional enthusiasm, not to mention the agency of other principles, over which an encroaching superstition had obtained unlimited controul, speedily gave it force, and in a short time filled even the poorest kingdoms with proofs of its love of splendor and power. The influence of Rome, in a word, was again experienced by people in very distant lands, whose insignificance and rudeness might have been expected to preserve them from any such visitations of the mistress of the world.

Various circumstances of a local nature prevented complete uniformity in the churches of different countries, though the identity of the origin of the style, and the common reference which they all had to the same revered models, secured a well marked resemblance. Thus, a certain form in the ground plan, constituting what has usually been called the Latin cross, was universally adopted in the construction of those edifices, and a peculiar arrangement of their more important internal members was almost as generally maintained. Greater latitude of fancy was allowed in the structure of the subsidiary appendages, and the kind and magnitude of the decorations were as numerous as the countries and provinces where the style was displayed. In general, it has been remarked, that the churches of Italy and the adjoining states were most modest in respect of ornaments, which seemed on the whole to augment with the distance from the capital. France and Britain may be said to have vied in profusion of spires, pinnacles, pediments of various kinds, and all the smaller decorations of this most prolific architecture. For comparisons of the most remarkable specimens in these and some other countries, and much curious information as to their history, with hints for determining their respective merits, we must refer the reader to the learned works of Milner, Whittington, &c. before mentioned. We shall confine our attention to a few particulars respecting the progress of this style, and of architecture in general, in our own island.

In Britain.—The Romans founded many cities and constructed a great variety of edifices in Britain. Some of the latter that were erected towards the end of their residence in it, when the religion of the empire had undergone a total change, were devoted to the services of the Christian church. But of their number, precise situations, magnitudes, and style, it is scarcely possible to obtain any satisfactory information. The affairs of this province, owing to the calamities of the Romans at home, had been long very indifferently attended to by the government, and probably were conceived very unimportant by those writers who engaged in the department of history. The Britons themselves had dwindled into insignificance, and had lost their patriotic spirit during a period of mortifying slavery. Few of them appear to have profited by the arts or sciences of their conquerors, and still fewer were either able or inclined to record particulars, which could only perpetuate the remembrance of their subjugation.

These unfortunate people, worthy of a better fate, on the Romans withdrawing from the island, early in the fifth century, found themselves exposed to the continual attacks of their ancient enemies in the north. Their chief concern was to repair and preserve the artificial barriers which some of the Roman governors had formerly thrown up for their defence; and this being insufficient, with such feeble unmilitary troops as they were able to muster, there was no leisure or means allowed them for less important occupations. The monuments, accordingly, of Roman art, were necessarily neglected. Such of them as remained were afterwards exposed to the desolating zeal of the Saxons, whom they called to their aid; but whose barbarity, ungenerous conduct, and peculiar hatred of the Christian religion, were no less injurious than the open and avowed hostility which they had been employed to avenge. Scarcely an example of the ecclesiastical edifices was permitted to testify the piety or taste of the former masters, or to remain as a model for imitation, when the abandonment of their own savageness and superstition, which afterwards took place, brought a new triumph to the Christian name and the cause of humanity. We have a striking description of the desolating conduct of those people in the words of Gildas, a writer who had the misfortune to witness it. The passage is given in Dr Henry's History of Britain. "A fire was kindled by the sacrilegious hands of the Saxons, which spread from city to city, and never ceased until it had burnt up the whole surface of the island, from sea to sea, with its flaming tongue. The walls of all the colonies were beat down to the ground with battering rams, and their inhabitants slain with the point of the sword. Nothing was to be seen in the streets, O horrible to relate! but fragments of ruined towers, temples, and walls, fallen from their lofty seats, besprinkled with blood, and mixed with mangled carcases." This language is no doubt hyperbolical, but it is impossible to dispute the reality of the facts to which it alludes. The island, then, once so embellished with the arts, and noted even in some of the chief places on the continent for the dexterity and skill of its workmen, was fast reverting to a state of ignorance and rudeness, well fitting the character of the people by whom it was now enslaved, and nearly two centuries elapsed before there appeared the smallest reason to hope for its redemption.

Under the Saxons and Danes.—The conversion of the Saxons, which commenced in the reign of Ethelbert, king of Kent, towards the close of the sixth century, and which, in the course of fifty or sixty years, was perfected throughout the heptarchy, formed an era in the history of England, and was marked by extraordinary efforts in the art of building. The policy of the monks, who had been instrumental in the change, pointed out the multiplication of churches and other religious edifices as a meritorious and necessary service, nor was the enthusiasm of the new disciples slack in doing justice to their instructions.

The materials principally used in these structures, at the time of which we now speak, was wood; but there were a few examples of churches composed of a more durable substance. Masonry, or the art of working in stone, appears to have been revived in England about the close of the seventh century. Biscop, or Biscopius, abbot of Westminster, and Wilfred, bishop of York, having frequently visited Rome, and travelled in various parts of Italy and France, acquired considerable taste and much information in it and some of the kindred arts, the practice of which they were enabled to introduce into their own country by means of workmen whom they had brought with them. Several cathedrals, built of stone, and much in the style then prevalent in Rome, were the consequence, besides the instruction of the natives in useful knowledge. But the example was not generally followed for a long period; and accordingly, even as late as the time of Alfred, buildings in stone were by no means common. When that illustrious prince undertook the improvement of his dominions, he was under the necessity of procuring his chief artificers from abroad; and it is pretty certain that the greater part of the many edifices erected by him were constructed of wood.

The frequent and harassing incursions of the Danes, not only retarded the progress of the art, but destroyed also many of its finest productions. That restless people rarely spared any of the churches, monasteries, or other buildings which they happened to meet with in their predatory attacks. As much of Alfred's life had been spent in opposing them, or endeavouring to recover his country from their vexatious power, so a great portion of his labours in architecture was directed to secure his subjects against their future designs. The art of defence was imperiously enjoined, and at first, of course, gave a peculiar character to his valuable undertakings. But the overthrow of his enemies permitting, at last, the full developement of his genius, he manifested the warmest regard for the interests of learning, good government, and commerce, and the highest talents for their effectual encouragement.

Under the Normans.—The Saxon princes who succeeded this illustrious man, appear to have been alike destitute of ability and inclination to copy his example; or if any of them professed either, it is certain that the distressed state of the country, occasioned by the continual and variously successful contests with the Danes, offered little or no opportunity for its beneficial exertion. In course of time, however, and in defiance of many disadvantageous circumstances, the art of building advanced in England. The connexion that had taken place with the Normans, an ingenious and well-informed people, long before the battle of Hastings raised William to the throne so eagerly and so fatally contended for, materially conduced to its improvement, and impressed some striking features on the larger edifices of this period.

The churches erected by this people were divided into three stories, consisting of the arcade, galleries, and windows; and the walls and pillars were made so strong and bulky, that no buttresses were thought necessary for their support. The western front, the decoration of which, it may be remarked, had long been the chief point of rivalship among ecclesiastical architects in general, was furnished with a portico or ambulatory, and the eastern front was made semicircular. The principal door-case shewed pilasters with carved capitals, and over the head of the round arch were placed mouldings of various kinds, as, indented, zig-zag, small squares, beads, &c. &c. The style was distinctly marked by want of harmony in the parts, massive columns, semicircular arches, usually springing from the capitals without the intervention of architraves, by such kind of ornaments as those above mentioned, and, in addition, in later times, by the practice of placing rudely carved figures in bas-relief under the arches of door-cases.

There are few if any entire buildings now remaining, which can be referred with certainty to the Saxon era; but the discriminating ornaments of the style are frequently to be met with. Mr Dallaway particularly points to the nave of the cathedral at Oxford, parts of the cathedrals of Durham and St Alban's, some door-cases and windows at Barfreston, near Canterbury, Tutbury in Staffordshire, Romsey, Hants, and Rochester. "Indeed," says he, "there is scarcely a county in England in which there will not be found individual churches still exhibiting Saxon, or, at least, Anglo-Norman remains. Of the Saxon, Gloucestershire boasts of two very perfect specimens, at Elkstone and Quenington. Door-ways of the early Norman are not unfrequently discoverable in monastic ruins. Those at Glastonbury, Malmesbury, and Castle-Acre priory, Norfolk, are particularly fine." On the whole, the Saxon style is to be considered as a rude imitation of the architecture which had prevailed in Italy after the declension of the art, and which was denominated by the monks, almost the only learned men of those days, 'Opus Romanum,' to designate its origin; and it cannot be doubted, that the intercourse which had long existed between the people of this island and the continent, chiefly on religious concerns, occasioned its adoption; though there be some reason also for the opinion, that certain remains of the ancient Roman edifices had a share in the effect.

Rapid advance after the Conquest.—The period from the conquest to the death of Stephen, that is, from 1066 to 1154, was richer in architectural productions than the preceding age. William I. whose mode of acquiring the throne, and arbitrary principles of government, exposed him to perpetual difficulties with his English subjects, found it necessary to erect many castles and forts, in order to retain his power, and prevent the consequences of their disposition to revolt. The Tower of London, the castles of Nottingham, Lincoln, Huntington, Cambridge, and many other places, are ascribed to his fears, and were scarcely sufficient for their removal. Measures of defence and oppression occupied him too much to allow his encouraging architecture in a different manner. The same remark is to be applied, with little modification, to the conduct of his successors through this period. The spirited opposition which all of them made, with the exception of the weak-minded Stephen, to the policy of the church of Rome and the dominion of the clergy, would have proved unfriendly to its improvement, had not the bishops, and higher orders of ecclesiastical officers, been rather stimulated to extend and secure their influence over popular feeling, in another manner than by their connexion with civil power. They devoted themselves to building, and laid the foundation of that splendid style which has given England so decisive a claim to consequence in the history of this noble art. Thus it is remarked by an author to whose researches we have been so materially indebt-

History.

ed in this treatise, that "no less than fifteen of the twenty-four English cathedrals still retain considerable parts which are undoubtedly of Norman erection." Not to mention many churches belonging to the greater abbeys constructed in this era, few of which unfortunately escaped the general demolition at the reformation, Mr Dallaway, whose words are just now quoted, gives the following enumeration of Norman bishops, who were either architects themselves, or under whose influence architecture flourished. "Gundulf of Rochester, (1077—1107,) whose works are seen at Rochester, Canterbury, and Peterborough. Mauritius of London, (1086—1108,) built old St Paul's Cathedral. Roger of Salisbury, (1107—1140,) the cathedral at Old Sarum. Ernulf of Rochester, (1115—1125,) completed Gundulf's work there; they were both monks of Bec in Normandy. Alexander of Lincoln, (1123—1147,) rebuilt his cathedral. Henry of Blois, bishop of Winchester, (1129—1169) a most celebrated architect, built the conventual churches of St Cross and Rumsey, in Hampshire; and, lastly, Roger, archbishop of York, (1154—1181,) where none of his work remains." Of the churches, the magnificence of which may be merely guessed at from the existing fragments, Mr Dallaway specifies those of Battel in Sussex, Reading and Cirencester, Malmesbury in Wiltshire, Dunstable in Bedfordshire, Castle Acre in Norfolk, Wenlock in Salop, and St Botolph's, Colchester.

A change in style appears to have taken place towards the close of this period, that is, in the end of Stephen's reign. The pillar, which had formerly been massive and single, became more slender, and was formed into clusters; and the arch, in place of being round, acquired a somewhat sharp or pointed appearance. These variations gradually increased, and more and more delicacy of execution, and lightness of proportion, obtained; but the minuter ornaments were preserved with little alteration. The fine style, to which such modifications gave rise, had arrived at great perfection in Henry III.'s time, as is shewn in those noble specimens, Salisbury and Ely cathedrals, and Westminster abbey, the two latter of which have been reasonably enough supposed, from their agreement in the chief proportions, to have been constructed on the same plan. It is improbable, indeed, that the width of the nave in each should have been 72 feet 9 inches, but by concert in the architects.

Discussion on the Origin of the Gothic.—Whence the hint, which occasioned so bold a deviation from the established manner, was derived, has been variously conjectured. Some French antiquaries have contended, that it appeared as early in their country as in England. The remark of Mr Dallaway affords, perhaps, as satisfactory a solution of both points as the nature of the question will admit. "If the Holy Land suggested ideas of this novel architecture, the French croissaders had the same opportunities of introducing it into France as ours into England, for they were associated in the same expedition. It has been said, that in the church of the Holy Sepulchre at Jerusalem no pointed arch was seen, but that in Moorish structures, equally obvious to those adventurers, it is frequent; for which reason it may be more directly described as Saracenic than as Gothic." A similar opinion had been long before maintained by Sir Christopher Wren, who proposed also the title now suggested as preferable to one which all modern writers had agreed to condemn; and it has been ably maintained by Mr Whittington and others, against an hypothesis of Dr Milner, which derives the whole style of pointed architecture from the intersection of semicircular arches, as frequently practised in England, for the sake of decoration, between the close of the 12th and the beginning of the 14th centuries. We cannot do justice to this part of our subject, without stating some of the arguments by which those opinions have been recommended. As most naturally connected with the brief historical view we have already given, and as having illustrated it in part by a series of figures, we commence with the system supported by Dr Milner.

Dr Milner's theory.—In the judgment of this writer, it is needless to have recourse to any foreign country for a discovery the gradations of which can be distinctly traced at home, from its dawn to its perfect completion, and that too among a people whose superiority in arts as well as arms over the inhabitants of those other countries might entitle them to such credit. It is his object, then, to prove that the Normans of the 12th century, especially such of them as enjoyed ecclesiastical distinctions in England, were possessed of this superiority, and that certain peculiarities in the edifices erected by them, had a tendency to lead, and did actually lead to the style of architecture in question.

The people with whom, in refutation of two theories opposed to his own, Dr Milner compares these Normans, are the Saracens, who, at the period adverted to, and for some time after, were in possession of the eastern countries visited by the Croissaders, and the Goths or Visigoths, who, after having conquered Spain as early as the 5th century, and been converted to the Christian faith, had built churches there in imitation of certain appearances of the groves in which they had been accustomed formerly to perform their Pagan rites in their native country, Scandinavia, and who employed in the work Saracen architects, "whose exotic style suited their purpose." As to the Saracens, Dr Milner appears to think they ought to be excluded from the merit of the invention, for two reasons, viz. because, "that throughout all Syria, Arabia, &c. there is not a Gothic building to be discovered, except such as were raised by the Latin Christians subsequent to the perfection of that style in Europe;" and because they did not arrive in Spain until the eighth century, when, "instead of building churches, they destroyed them, or turned them into mosques." With respect, again, to the Goths themselves, no claim set up in their behalf, though aided by the learning and authority of Bishop Warburton, has had speciousness enough to give trouble to the supporters of almost any other theory. But even admitting them to be more considerable, it is evident, from what has already been said, that they derive a great part of their validity from the supposed but disputed ingenuity and good offices of another people. The chief *fact* by which Bishop Warburton's notion is countenanced, for it would be idle to attend to his reasonings or surmises, is the circumstance of some pointed arches being found in the mosque of Cordova, said to have been finished about the year 800. But then, it is not certain that these arches, which are formed by the intersection of two segments of a circle, are really part of the original structure, and it is known that the edifice has been more than once altered by the Mahometans. It would be unfair, therefore, to draw any inference from the fact, till the precise date of its appearance in the present form were correctly ascertained. The existence of pointed arches in the Moorish palace at Granada, called the Alhamba, is still less justly adduced in defence of the same cause, as this building was not erected till the year 1273, when the pointed style may be said to have been established in Europe.

Having disposed of those rival pretensions, Dr M. confidently brings forward his Norman prelates resident in England, as more deserving of notice, and specifies particularly and circumstantially the steps by which they were progressively advanced to the honour assigned them. Among his favourites are Roger of Sarum, Alexander of Lincoln, Mauritius of London, Roger of York, and, above all, Henry of Winchester. The successive improvements of each of these, he tells us, "were of course adopted by the rest," and they all contributed to change the Norman into the Gothic architecture. In what manner they did so, it is of some consequence we should be informed.

The Normans, who affected height no less than length in their churches, in order to obtain it piled arches and pillars on each other, so as at times to form three stories, an example of which is to be seen in Walkelin's work in Winchester cathedral. An imitation of such accumulated masses was frequently practised in the masonry of plain walls; and it was usual by way of ornament, and for the sake of variety, to cause the plain round arches to intersect each other, as may be seen in the upper part of the south transept of the same edifice, which affords probably the first instance of this interesting ornament in the kingdom. It was not, Dr M. thinks, till De Blois, the architect of St Cross, near Winchester, conceived the idea of opening the comprehended spaces for the purpose of windows, that these people were aware of the happy effect of such intersections. The form of both windows and arches now underwent a change; they became long and narrow. This again required the pillars on which they rested to be proportionally tall and slender, and a material of firm texture to be used for their composition. Purbeck marble, generally adopted for the purpose, being found too weak for the weight to be sustained, the shafts were multiplied, and hence arose the clustered column so striking in this style. As the windows, from the manner in which they were formed, were in general very narrow, it was thought necessary at times to place two of them close together, and that frequently under one common arch, of which we have instances in different parts of De Lucy's work in the same cathedral, and in the lower range of the windows in the church of Netley abbey. Such an arrangement, it is obvious, occasioned a blank, or dead space, between the heads of the conjoined windows, which was accordingly planted with a trefoil or quatrefoil, one of the ornaments anciently employed in porches and other places. This kind of decoration soon became prolific. It was the source, in short, of those cinquefoils, circles, squares, fans, Catherine's wheels, &c. so conspicuous in Gothic windows. Such ornaments were not long confined to their original situation. They were applied also to the pointed arches on the outside of buildings, which frequently were made to terminate in a trefoil. The buttresses even, that were erected externally in aid of the walls, must have their appropriate pinnacles similarly beautified; and the pinnacle again, still advancing in the mighty effort of ambitious improvement, became at last a spire. "Thus, we see, how naturally the several gradations of the pointed architecture arose one out of another, and how the intersecting of two circular arches in the church of St Cross may perhaps have produced Salisbury steeple."

Such then is the theory, in few words, which Dr Milner has advanced in his Essay "On the rise and progress of the pointed arch," contained in his History and Survey of Winchester," to which we must refer for information as to the facts and reasoning brought forward in its support. Before proceeding to consider a very different theory, we have to notice a distinction endeavoured to be established by the same author, in the manner or appearance of this style. According to him, the Gothic architecture is as susceptible of a division into orders as the Grecian, and these are also three in number, each of which is essentially characterised by the degree of inclination of the lines forming the pointed arch.

Different orders of Gothic.—In the *first order*, the arches are very acute, and the pillars for the most part heavy and massive, such as are found in Saxon or Norman buildings, but sometimes having a faint resemblance to the clustered column, groins of simply intersecting ribs, and windows without mullions, or having only a single bisecting one, and ornamented with a single trefoil, quatre-foil, or other simple flower. The east end of Canterbury cathedral furnishes an example. We have other instances in the cathedral of Lincoln (the west end), Salisbury throughout, and in the transepts of Westminster and York. This order is to be traced from about the beginning of Stephen's reign, till near the end of the 13th century.

In the *second order* are exhibited arches, forming an equilateral triangle, clustered columns generally formed out of one stone, and having what are called historic capitals, windows magnificently enriched with a variety of ornaments, decorated groins, mullions reaching to the bottom of their story, shafts of the main cluster supporting the springers of minute arches, &c. all indicative of a grandeur and freedom bordering on luxuriance, but withal extremely delicate and pleasing. There are noble specimens in the choir and nave of Yorkminster, the naves of Westminster, Canterbury, Winchester, Exeter, and St Stephen's Chapel, Westminster. This order prevailed from the end of the 13th to the middle of the 15th century.

The *third order* is easily discriminated by its depressed obtuse angled arches, pendant capitals, greatly perforated walls, and an extravagant profusion of tracery and other fanciful decorations, much more calculated to excite surprise and a feeling of perplexity, than to gratify a refined and correct taste. This order, which has justly enough been considered as marking the decline of the style, reached from the end of the 15th to the middle of the 16th century. It is to be seen in Henry VII.'s chapel, Westminster, certainly a most extraordinary production, King's College chapel, Cambridge, and St George's chapel at Windsor.

The sum of Dr Milner's opinions, then, may be given in a short compass. The pointed architecture grew out of the simple pointed arch, between the end of the 12th and the early part of the 14th century. The pointed arch itself was discovered by observing the effect of those intersections of semicircular arches which preceding artists employed to ornament ecclesiastical edifices. We are indebted for both discoveries, that is, for the origin and cultivation of the pointed style, to our own ancestors, the Anglo-Normans and English. Lastly, There are three orders of this style, as plainly distinguishable from one another as the orders of the Grecian architecture, and having their respective members, ornaments, and proportions.

Mr Whittington's theory.—For a very different view of the whole subject we shall have recourse to a recent publication by Mr Haggitt, rector of Ditton, Cambridgeshire, who ably supports Mr Whittington's sentiments. According to Mr W. the pointed arch existed in France before the 12th century, and that not accidentally, or by way of ornament merely, but as an *integral part* of several structures, and constituting a prominent feature in them; the pointed style, therefore, could not have its origin at the period assigned by Dr Milner, or be discovered in the manner and place which he has specified. It is endeavoured, in short, to make it appear, that the French had attained to a high degree of perfection in this style, half a century before the English had constructed any similar work of *comparative* excellence, and that consequently the latter are not at all entitled to the merit which Dr Milner awards them as its discoverers and earliest promoters. The evidences of this fact, cited in Mr. Whittington's work are these four examples of the pointed arch: 1st, The *crypt* of the abbey church of St Denis, which was completed by Charlemagne as early as the close of the 8th century; 2dly, The eastern end of the choir of the abbey church of St Germain des Pres, finished at the beginning of the 11th century; 3dly, The choir of the Benedictine church of la Charité sur Loire, completed before the close of the same century; 4thly, The chapel of the Apsis, and some part of the eastern arcade of the church itself of St Denis, which were the work of abbot Luger in 1144. The greater part of this last edifice was rebuilt in 1231; but as the pointed arch is visible in every part of what remains of the ancient work, it is with propriety brought forward as a legitimate example. Other evidences of a similar kind, it is believed, might have been mentioned; but the caution and scrupulousness of Mr Whittington would not suffer him to advance any instance which he was unable to substantiate by a distinct record. These four may be judged sufficient, especially when it is considered that Dr Milner himself appears totally at a loss to discard them. The last of them, indeed, is the only one with which he attempts feebly to contend. Even giving it up, then, it seems to follow of necessity, that "the pointed arch existed in three important edifices of France before it was known in England."

It is to meet this decisive conclusion that Dr Milner tells us of examples of pointed arches formed by intersection, and introduced as ornaments upon the walls of English churches in the 12th century. But at all events these correspond as to date with the last only of Mr Whittington's four examples; and then they are not instances of the pointed arch used as an essential feature, but are mere decorations which may be proved to have been "common to the Lombard churches of that and of a still earlier period through a great part of Europe." Whereas, on Dr Milner's own hypothesis, two out of the three admitted examples adduced by Mr Whittington, are full and complete instances of the Doctor's *first order of the pointed style*, that is to say, such instances of it as the choir of Canterbury, which was not built till nearly two centuries after the first of the churches alluded to, and one century after the second. Before concluding this part of our statement, it is incumbent on us to mention another example of the priority of the French in the use of the pointed arch, to be added to the four already specified. It is the abbey church of Clugny, begun in 1093, and finished in 1131, of the interior of which Mr Hawkins has given two views in his work on the History, &c. of Gothic Architecture, lately published. The opinion is a very probable one, that Henry de Blois, who afterwards exhibited the pointed arch in his hospital of St Cross, as was formerly remarked, actually acquired his knowledge of it during his residence in this abbey, where he passed his early years as a monk, at the very time that the church belonging to it was erecting. A presumption, at least, thence arises, as to the introduction of this style into England, which a warm partisan could scarcely fail to cherish. Nor is it immaterial, perhaps, to notice, that the church of Notre Dame in the capital of France, entirely a Gothic building, was begun in 1161, and was so far completed in 1181 as to be consecrated by the Pope's legate.

Probably derived from the East.—But clearly as we think it may be demonstrated, that this style was adopted in France sooner than in England, we see no reason to imagine that it originated in that country. This leads us to make a few remarks on the probability of its having been received from the east in the course of the Crusades.

In the first place, then, if we except a few desultory instances of pointed arch, which, it is not unlikely, were suggested by the information of some of the earlier pilgrims to the Holy Land, it is very certain that none of the principal features of this style existed in Europe anterior to the time of the first crusade, which ended with the capture of Jerusalem in 1099. In this expedition few of the English were engaged, and but a small part returned to their native country. A similar observation is to be made respecting the second crusade, which took place in 1146, under the guidance of the Emperor Conrad and Louis the Seventh. It is not certain, indeed, that any English force was associated in it. Not so, however, in the third crusade, which commenced in 1191; there Richard I. and many of his subjects acted a conspicuous part.

In the second place, this style appears to have arisen in different countries of Europe during the course of these expeditions, and that, too, very much in the proportion and order in which they were engaged in them. Thus France exhibited various instances of it soon after the termination of the second crusade, but England not till after the return of Richard from the third; a difference which the circumstance above stated may be allowed to explain. It is indeed a very important fact in this question, as is noticed by Mr Haggitt, "that during the last twenty years of the 12th, and the first thirty years of the 13th centuries, Gothic architecture arose and flourished in all the principal countries of Europe; in France, in Germany, in the Low Countries, in Spain, in England, in Italy, and in Sicily;" and it certainly appears something more reasonable to ascribe so general an adoption of it to the influence of an agent common to the whole, than to imagine what, on any view of the matter, is not susceptible of proof, that one of these nations having invented the style, became the pattern to which the others conformed. It is almost inconceivable, in reality, that this latter could have been the case, and yet that there should exist no historical evidence by which it can be substantiated.

Thirdly, If there be reason to determine that the principal features of the pointed style existed in the East previous to those expeditions, it will appear very probable, the two preceding circumstances being taken into account, that this mode of architecture was one of the consequences resulting from them. The proof of this fact, indeed, is almost decisive of the controversy. Dr Milner, aware of this, is shocked at the idea of deriving so beautiful and ingenious an art from the "ruthless Saracens," and attaches unlimited confidence to the negative incident of Pococke, Norden, and Shaw neither making mention of pointed arches, nor giving representations of them in their accounts of those eastern countries which they had visited. Mr Haggitt, on the other hand, establishes the competency of this people, from their general character in history as the cultivators of the arts and sciences, and the well-known magnificence and number of their architectural productions; and he both accounts for the silence of the travellers just now mentioned, and opposes to it the direct and positive testimony of more recent observers. In our judgment he has completely succeeded in both points; and accordingly we have not the shadow of a doubt, that the chief features of the pointed architecture, as a style, are really to be found in the East. An impartial reader of Mr Haggitt's Second Letter cannot resist this conclusion; and hence the only remaining question to be determined respects the antiquity of the monuments which display them. Here, too, it appears, that the evidence adduced by this gentleman is entitled to high consideration, if not productive of entire conviction. On the whole, then, we do not hesitate to award the full amount of his claims in behalf of the opinion he has espoused, or to admit the correctness of his concluding statement as to the success of his inquiries. "I have shewn," says he, "that there is at least no moral improbability in the eastern origin of pointed architecture: I have endeavoured to account for its not appearing in this island sooner than it did appear, and for its introduction at the termination of the *third crusade:* I have also shewn, that remains of pointed, or Gothic architecture, actually exist in Syria, Palestine, and Egypt; and that there are strong reasons for assigning some of those remains to an age long anterior to the crusades."

Before concluding this subject we may suggest, that though his opinions as to the relative times of its appearance be disproved, yet the idea of Dr Milner respecting the mode in which the pointed arch originated, is quite reconcileable with the fact of its superior antiquity both in France and the East. It is rather strange that this remark has not been made before by any of the combatants. But we are far from deciding as to its correctness. Another observation occurs, perhaps no less entitled to respect. May not the pointed arch have resulted from the substitution of several pieces, in place of the two rafters or stones opposed to each other, in the manner described when speaking of the origin of the arch, after the safety and the beauty of the circular form had attracted so much regard as to modify the existing taste? This opens a field for inquiry, as far as we know not yet entered on, and might carry back the principles of Gothic architecture to a still earlier period than the theories now stated have assumed. The reader will find an interesting series of comparisons between French and English cathedrals, &c. in Mr Whittington's work. Mr Dallaway's Observations on English Architecture will supply him with many curious particulars respecting the latter.

English style varies.—The equally clustered column with a low sharp arch, prevailed in Edward III.'s time. The chapel of Our Lady, attached to Ely cathedral, is a fine specimen of the style of this period. Becket's Crown, in Canterbury cathedral, probably suggested the idea of the Louvre of Ely and Canterbury. To the crosses erected by Edward I. in honour of his consort, has been attributed the introduction of the elaborate canopies and minute decorations of tombs and shrines. These ornaments soon became excessive. The earliest example of this sort of workmanship, generally termed "filligraine," is the choir of York cathedral. Additional embellishments were sought about the middle of the 15th century, some of them abundantly whimsical and capricious, as may be seen in the armorial ensigns of honour on roofs, and the spandrils of internal arcades. They were also commonly appended to market crosses and the gateways of abbeys. Crosses answered, in these times, the double purpose of devotion and commerce, and it was the fashion to adorn them in the most luxuriant manner. That particular style which has been properly enough denominated the "Florid Gothic," seems to have prevailed from the beginning of the reign of Henry IV. to the end of that of Henry VII.; and it is no doubt a singular circumstance, that architecture flourished so extensively during the tempestuous times of the wars between the houses of York and Lancaster. Of the edifices of this period we may mention the choir of Gloucester, the sepulchral chapel adjoining the parish church at Warwick, that at Westminster, King's chapel at Cambridge, the royal chapel at Windsor, and the abbey church at Bath, which, though finished a little later, is properly referred to this era. The reformation, it need scarcely be told the reader, destroyed more edifices than it spared. How great, then, reckoning from the number and kind of those which remained, must have been the zeal, and intelligence, and taste, which animated and directed the pious patrons of English ecclesiastical architecture!

The reign of Henry VII. in which the basis was laid of a firm and undisputed government, was peculiarly favourable to this art. It has been termed, indeed, the grand æra of handsome parochial churches, which sufficiently signalizes the amount and kind of service given. The style, though becoming gradually more venturous and indulgent, was hitherto unmixed. In the succeeding reign, particularly towards its close, a combination of Gothic and Grecian manners was destructive of the real beauties which either possessed separately. The proper remedy for the evil was discovered long after in the revival of classical architecture, as recommended by the learning of Sir H. Wootten, and illustrated by the genius of Inigo Jones and his disciples.

Progress in Scotland.—Here we may make a remark or two respecting the progress of ecclesiastical architecture in Scotland. This country, it is probable, had not so much as one stone church at the commencement of the 8th century. But a wooden church built on the island of Lindisfairn, in Northumberland, A. D. 652, is said to be constructed *more Scotorum*, from which it may be inferred that this people were well acquainted with the use of other materials at this period, Naitan, king of the Picts, applied by letter to the abbot of Weremouth, A. D. 710, for the assistance of masons to erect a stone church in his kingdom, and his request, Bede tells us, was granted. The churches of Old Melrose, Coldingham, and Tynningham, are imagined to have been among the first buildings of the kind in this kingdom. The art did not prosper much till the reign of David I. when it was carried on to a greater degree than the poverty of the country might seem to have allowed. No less than twelve considerable edifices, destined to religious purposes, have been ascribed to this prince, amongst which are the four cathedrals of Glasgow, Dunkeld, St Andrew's, and Aberdeen. These, and the other buildings now alluded to, were probably all erected between 1125 and 1154, a striking fact in the concerns of so small a state, and not paralleled, we believe, in any other period of its history. Of the subsequent structures of this kind may be mentioned the abbey of Aberbrothwick, founded in 1178, the Pluscardine priory in Moray, 1230, and the collegiate churches of Dunbar in 1342, Dunglas, 1403, and Roslin, 1446. "Of Gothic architecture in Scotland, (says Mr Dallaway,) the most beautiful pieces which remain entire are Melrose abbey, (rapidly decaying, alas!) the cathedral at Glasgow, Lincluden college, near Dumfries, the chapel at Roslin near Edinburgh, and that in the palace of Holyrood, (now a ruin,) the last mentioned of which was founded about 1440, by king James II. of that realm. Their sides are flanked by flying buttresses, like those at Westminster, but with a happier effect, because in a purer style."

Progress of Castles, &c. in Britain.—The history of castellated and domestic architecture in Britain, demands some notice. The Romans built many military structures in the various provinces which they had conquered, and of these, it is probable, the Saxons, who succeeded to them, availed themselves, in order to retain possession of the country. Long acquaintance with the feudal system had accustomed the Normans to the notion that a castle was essential to every large estate. This did not abandon them on their coming over to England, as is evident from the numerous remains of their fortresses still to be met with. The chief peculiarity in these buildings is the *keep*, usually a square tower of great height, or a circular one much lower but of considerable diameter, and accessible by steep stone stairs. The walls, which were of great thickness, admitted a winding stair-case, galleries, and chimnies, the oven, the well, &c. and had an opening at top for the admission of light and air to the dungeon at the base, in which it was customary to confine prisoners. The ground-floor was without light; the second obtained it through small loop-holes; but the third, in which was the state apartment, had the benefit of large round-arched windows, so contrived as not to be looked through from within, nor penetrated by missile weapons from without. Various contrivances rendered these forts tolerably secure, even after the adjoining buildings were either taken or destroyed. Famine, of course, proved an invincible opponent. Gundulph, bishop of Rochester, after the conquest, is said to have contributed much to the strength and beauty of the established mode of defence. His plans were gradually improved in subsequent times, especially in the period between the reigns of the second and third Henry. But the chief amendment was owing to the observations which Edward I. made during his crusading visit to the Levant and the Holy Land, where the architecture of defence had arrived at great perfection. The castles of Caernarvon, Conway, Harlech, and Aberystwith, all in Wales, were erected by this prince. Scarcely a vestige of the last is discoverable, but the others still claim admiration. Many other castles in this territory had their origin in the resolution of Edward's chief followers to preserve the divided fruits of his successful invasion.

Hitherto, and for some time after, the principal object aimed at in these fortresses was impregnability. The reign of Edward III. presented a new feature, in a degree of elegance and habitable comfort, to which former generations were strangers. The example of this monarch at Windsor, may be said to have excited a rivalry among his barons, many of whom were the abler to engage in it, in consequence of the wealth acquired by the ransom of prisoners taken in the battles of Poictiers and Cressy. The improvements now alluded to were continued and extended to the time of the termination of the contests between the houses of York and Lancaster,—a period rich in castellated edifices, whose ruins now form an interest of the highest kind in many of our choicest landscapes.

In the tranquillity that succeeded this long dissension, the forbidding features of the castellated style became less striking, greater regard was paid to embellishments, and those baronial mansions which still retained a military appearance, displayed, at the same time, the magnificence and convenience of private dwellings. Domestic and military architecture, in short, were blended together in various degrees throughout the reign of the Tudor family, the increasing security of the public peace at last giving preponderance to the former, which in many cases merely acknowledged a kind of relationship with the latter by its useless battlements, insignificant parapets, turrets, &c. &c.

The employment of brick in place of stones of various kinds, is perhaps nearly coeval with the conversion of castles into commodious houses, and became more common as the necessity for defence diminished. But in certain parts of the country the abundance of the latter material decided. It has been supposed that the use of brick, which was so frequent with the Romans who resided in England, was not revived till the reign of Richard II. The walls of the feodal castles of early times were commonly faced only with hewn stones, the intermediate parts being filled up with pebbles, rubble-stones, &c. Flints squared in a particular way were often used for outside walls, especially in Henry VII.'s time. When the condition of public affairs permitted a regard to internal decorations, it became usual to cover the walls of state chambers with wainscot, which was either painted in fresco, or hung with arras or tapestry. The large halls also, which formed an essential part of the castles, afforded a favourite subject for ornament. In painted glass, carvings of different kinds, and all sorts of beautifying contrivances, some castles are supposed to have vied with the churches of the same period.

Revival of Roman style in Britain.—The partial introduction of the Roman style, about the middle of the 16th century, co-operated with the change of manners attendant on long tranquillity, in occasioning an abandonment of the peculiarities of the military architecture. Holbein took the lead in this transformation, confining himself chiefly to the porticos and portals of houses. He was followed by John of Padua, who built Somerset-house and Longleat, both in a mixed style. The first house, entirely Italian, according to Mr Dallaway, was erected by Sir Horatio Palavicini, at Little Shelford, in Essex. Queen Elizabeth's reign produced several respectable architects and many magnificent houses. Of the more remarkable productions which appeared towards the close of the 16th, and the commencement of the following century, may be specified, Burleigh-house, Audley-end, Holland-house, Campden-house, and Knowle. Mr Dallaway has well described the peculiarities in the style of this period. "The vast dimensions of the apartments, the extreme length of the galleries, and the enormous square-windows, are the leading characteristics of the manner of building during the reigns of Elizabeth and James I. The ornaments, both within and without, were cumbrous, and equally void of grace and propriety. Nothing could exceed the heaviness of the cornices and cielings, wrought into compartments, or the awkward intersection of the passages. The hall retained nothing of the Gothic description, excepting its size and bay-window; being very frequently merely a large room, including the whole space of the house from the base to the roof. Instead of battlements and pinnacles, the parapet was broken into numerous pediments, not exactly conical or angular, but of a form too capricious for description."

Modern innovations.—This heavy style of building, which distinguished the reigns of Elizabeth and her successor, gave way to the lighter taste and chaster conceptions of Inigo Jones and his scholars. To their influence on the public mind, in recommending the adoption of classical architecture, we owe much of that elegance and highly-wrought convenience so conspicuous in modern English houses. Their labours, it is probable, would have proved more immediately important, had not the distressing calamities which afterwards afflicted the kingdom afforded more imperative considerations. Many of the edifices ascribed to Inigo Jones were finished from his plans, though not built under his own notice. Of his genuine works may be mentioned Stoke-park, in Northamptonshire, Castle-Ashby, Charles I.'s picture gallery at Whitehall, the Queen's house in Greenwich-park, Lindsey-house in Lincoln-Inn Fields, the Grange in Hants, and the Banqueting-house at Whitehall.

The restoration of Charles II. seems not to have been propitious to architectural purity. Some very injudicious attempts were then made to reconcile the Gothic and classical manners. The principal architects, in general, possessed more science than taste. An intimate acquaintance with the fine models of antiquity was required to correct their judgment as to the sources of the beautiful in the art. But it was long before this remedy was any way effectually applied. The names of two noblemen, Pembroke and Burlington, enlightened patrons of the art, merit distinction for their contributions towards its improvement, as well as those of Wren and Vanburgh for their official services. Lord Leicester, in a subsequent period, seems to have possessed equal refinement and strength of conception. Indeed, for sometime, the chief improvements in our national architecture were owing to the classical studies of persons who were alike removed from the prejudices of professional men, and the necessity of accommodating themselves to public opinion. We have still more recent examples of the same truth.

Present state.—Greater intimacy with ancient models, principally effected through the labours of Wood and Dawkins at Palmyra and Balbeck, Stuart, Revet, and others, in Greece, &c. has occasioned the abandonment of the debased Roman manner; but the Gothic and mixed styles are still in repute. The recent discoveries in some of the subsidiary sciences have materially influenced the internal arrangement of houses, whilst a judicious regard to what may deserve the name of salutary luxury, and perhaps a still greater regard, not so commonly justifiable, to splendour of appearance, together with the perfect absence of every defensive idea, have been productive of an amplitude of dimensions, and a boldness of aspect quite unknown to former times, and, as far as we know, to other countries. It would be easy, indeed, in the political history of Europe for the last half century, to point out reasons why architecture has been more highly cultivated in Britain than in any other kingdom. We are not aware of any causes likely to arrest its progress; nor do we apprehend its deterioration, unless from an evil agent, to which we have more than once alluded, but against which we are furnished with an effectual security if we chuse to avail ourselves of it, in the perpetually renewed display and diligent study of those models of harmonizing beauties, which so many generations of mankind have willingly agreed to admire.

Explanation of Plates.

Plate 11. Fig. 1—9. illustrate the strength of materials; Fig. 10. the construction of arches; Fig. 11—21. the constructions of roofs; Fig. 22. a Norman roof.

Plate 12. Fig. 1. The old roof of St Paul's church, Covent-Garden, London; Fig. 2. The new roof; Fig. 3. The roof of Islington church, near London; Fig. 4. A proposed improvement on the same roof; Fig. 5. Roof of the chapel of Greenwich hospital; Fig. 6. Roof of Birmingham theatre; Fig. 7. Roof of Drury-lane theatre; Fig. 8. and 9. Parts of its construction; Fig. 10. Remarkable roof of the Riding-school, St Petersburgh; Fig. 11. Dome of St Paul's, London; Fig. 11, 2d.—20. Illustration of the construction of wooden bridges.

Plate 13. Fig. 1—8. Construction of the centering of different bridges; Fig. 9. Sunderland bridge.

Plate 14. Plan and elevation of different bridges; the wooden bridge over the Don, near Aberdeen, consists of a single arch of 109 feet span; the three ancient Roman bridges are in Rome or its vicinity; the bridge of Orleans in France, designed by M. Hupeau, and remarkable for its simplicity and elegance, consists of nine arches; the middle arch is nearly 107 feet span, with a rise of 30 feet, the arches next the abutments have 98 feet span and 26 feet of rise, and the remaining arches are in proportion. The whole breadth, including the parapets, is 49 feet. This fine bridge was begun in 1750, and was finished in ten years.

The bridge over the Tay at Dunkeld, which is reckoned one of the finest in Scotland, consists of five large arches, and two on the land sides of a smaller description. The middle arch is 90 feet span, with a rise of 30 feet. The breadth over the parapets is 27 feet.

The Strand or Waterloo bridge over the Thames at London consists of nine arches, of 120 feet span each. The piers are 20 feet thick; the breadth within the parapets is 42 feet; the road-way is 28 feet broad, and the footpaths are seven feet broad each. A considerable part of the foundations of the piers and of the arches is built with the fine sandstone from Craigleith quarry near Edinburgh. Other parts are constructed of Cornish granite, and the outside or casing of the entire structure is of the same material, but the balustrades are formed of the beautiful grey granite from Aberdeen.

Plate 15. Fig. 1. Shews the different parts and divisions of a column and entablature in the Tuscan order; Fig. 2. Illustration of the Doric order; Fig. 3. Character and dimensions of the Ionic order; Fig. 4. Character and proportion of the Corinthian order; Fig. 5. The Composite order.

Fig. 6. 7. 8. 9. 10. 11. 12. Illustration of Sir James Hall's theory of the origin of Gothic architecture.

Fig. 13. Arched entrance to the north aisle of Peterborough cathedral, illustrating the Saxon capital and *chevron work* or zig-zag ornaments.

Fig. 14. An arch in Norwich cathedral, adorned with *billet*-moulding, and a spiral band on one of the columns.

Fig. 13. 14. 15. 16. 17. illustrate the origin and progress of the pointed arch.

Plate 16. Fig. 1. St Paul's, Covent Garden, London, which is reckoned a good example of the Tuscan order. No ancient specimen is known.

Fig. 2. Doric portico at Athens, with four fluted columns, supposed by some to be the remains of a temple dedicated to Rome and Augustus, but by Mr Wilkins to be the entrance to a market-place. This is esteemed one of the best examples of the ancient Doric order applicable to private edifices.

Fig. 3. Temples of Erectheus, of Minerva Polias, and Pandrosus, at Athens; A, the temple of Minerva, at other end of which is the temple of Erectheus; B, is the portico of both temples. The temple or cell of Pandrosus is adorned with caryatides, one of which, supporting the corner of the entablature, was removed by Lord Elgin, and is now in the British Museum. This fine example of the ancient Ionic is copied in the portico of the county-hall, now erecting (1816) in Edinburgh.

Fig. 4. An example of the Corinthian order, taken from the remains of the temple of Jupiter Stator at Rome, which is greatly celebrated for its rich decorations.

Fig. 5. View of an ancient Sarcophagus.

Fig. 6. Amphitheatre at Pola in Istria, of an elliptical form. The length is 436½ feet, the shorter diameter is 346 feet, and the height about 100 feet, and is divided into three stories.

Fig. 7. The Trajan column at Rome is seen in the distance.

Plate 17. Fig. 1. Temple of the Winds at Athens, is constructed of marble, and of an octagon form, on each side of which is sculptured an emblematical representation of the wind which blows against that side, and on the top was a conical piece of marble, and surmounted by a triton, holding a wand in his right hand, so contrived that the wand points to that side from which the wind blows. The roof of this building is remarkable for its elegance. Under each of the figures, which are fine pieces of sculpture, is a sun-dial; and

RHEIMS CATHEDRAL.

Plates.

a stream of water was conducted to a clypsedra in the interior of the edifice to mark the time in the absence of the sun. The height is about 44 feet and the diameter about 26 feet.

Fig 2. The Parthenon at Athens, one of the finest specimens of ancient architecture, is peculiarly distinguished for its grandeur, simplicity, and sublimity. The length when entire was 217 feet, the breath 101 feet; the number of the columns 58, the height 34 feet, and the whole height of the order 45 feet. During the siege of Athens in 1687 by the Venetians, the Turks converted the Parthenon into a powder magazine; a bomb fell into it, kindled the powder, and blew it up. Eight columns of the east front, and some of the side porticos yet remain.

Fig. 3. The Choragic monument of Lysicrates, which is commonly called the Lantern of Demosthenes, stands near the east end of the Acropolis at Athens, is reckoned a fine specimen of ancient art, in the Corinthian order, and was erected about 330 years before the Christian era, and in the time of Alexander the Great, in commemoration of a musical entertainment exhibited by Lysicrates. It is of a circular form, about 8 feet in diameter, and 34 feet high; and is composed of a basement, colonnade, and cupola.

Fig. 4. Temple of Vesta at Tivoli, of which eleven out of eighteen columns of a circular colonnade remain, when it was described by Desgodetz. Great part of the wall, containing the door and one of the windows, was also entire. The columns are two feet four inches at the base, and they are channelled with 24 flutings. This beautiful fragment of ancient art stands opposite the cascade of the Teverone, and is five or six leagues from Rome.

Fig. 5. and 6. Plan and elevation of the Pantheon, now called the Rotunda, at Rome. The Pantheon, which was built by Agrippa, the son-in-law of Augustus, has been always regarded as one of the finest specimens of Roman architecture, and, fortunately, it is one of the most entire of the ancient edifices. It was dedicated, as the name imports, to all the gods. Pope Boniface IV. dedicated the Pantheon to God, by the name of the Blessed Virgin and the Holy Martyrs. In 1627, Pope Urban VIII. caused two columns of the portico, which had been removed, to be replaced, and the capitals which were wanting to be restored, the front to be repaired, and the rubbish cleared away around it, by which the two upper steps to the portico were discovered.

Plate 18. Fig. 1. A fine modern specimen of the Grecian Doric, in the Court-house, Public Offices, and Gaol of Glasgow, erected in 1810, at an expence of L.35,000, from the design of the late Mr William Stark, architect, whose pure, classical taste is abundantly conspicuous in other public edifices in the same place, as the Hunterian Museum and the Lunatic Asylum. This view is copied from an elegant original drawing by Mr Stark himself, for which we are indebted to the liberality of his relative Mr George Thomson, of the Trustees' Office, Edinburgh. In justice to the ingenious artist, it ought to be noticed, that the elevation of the building is less by several feet than was originally intended by Mr Stark; and this depressed appearance, which diminishes the grandeur of effect, is farther increased by the surrounding parapet-wall and railing, behind which the colossal steps, which form the ascent to the portico, are concealed. But this last addition was no part of Mr Stark's design.

Figs. 2. 3. and 4. Elevation, plan, and section of the Church of St Genevieve, at Paris, the design of which is taken from the Pantheon at Rome. The columns, which are of the Corinthian order, are $5\frac{1}{2}$ feet in diameter, and, including the base and capital, 58 feet high, French measure. At the commencement of the revolution, this edifice was destined, under the name of the French Pantheon, to receive the ashes of patriots and warriors; its ancient name was restored during the reign of Bonaparte, and the underground part of the building was limited to the same use. In the original design, Soufflot, the architect, proposed the dome to be surmounted by a lantern, for which a colossal statue of Fame, in bronze, is projected, and a model in plaster, of 25 feet in height, has been executed by Dejoux, the statuary; but it is feared that the dome is not fit to receive that additional weight.

Plate 19. View of the Episcopal Chapel, in York Place, Edinburgh, an example of modern Gothic, from a design of Mr Elliot, architect, who obligingly permitted us to copy his original drawing. The whole expence of this edifice, which accommodates 1000 persons, is estimated at L.12,000. The area which it occupies is 124 feet in length, and 73 feet in breadth. The height of the nave on the south side, to the top of the battlements, is $51\frac{1}{2}$ feet, and on the east and west fronts, to the top of the cross, 62 feet, and the height of the side aisles is $33\frac{1}{2}$ feet. The octagonal towers rise to the height of $81\frac{1}{2}$ feet. Including the altar, the length of the nave is 106 feet, the breadth 26 feet, and the height 35 feet. The altar window, which is to be decorated with stained glass, is 32 feet 8 inches from the sole to the top of the arch, and the breadth is 13 feet 6 inches. The ceiling of the nave, which is to be a flat Gothic arch, is to be enriched with Gothic fret-work; and the cielings of the side-aisles are to be decorated in a similar manner. The pulpit and fronts of the galleries are to be richly finished with oak in characteristic style, and the whole is to be completed in 1817.

The Chapel of Roslin, near Edinburgh, was erected in 1446, and exhibits a singular mixture of various styles. The view on Plate 19. shews the rich internal decorations of the edifice. Seven columns on each side, supporting pointed arches, divide the nave from the side aisles; and over them, in the middle aisle, which is highest, is a row of windows. The cieling, capitals, architraves, and key-stones, are covered with a profusion of sculpture work, representing foliage, flowers, scenes from sacred history, texts of scripture, intermixed with grotesque figures. The Apprentice's, or Prince's Pillar, as it is sometimes called, has been always admired for the richness of its ornaments, and the exquisite neatness of its sculpture. It is peculiarly distinguished by four spiral wreaths of flower-work and foliage, all different in design, and so finely executed as to resemble lace. The story of Abraham offering up Isaac is represented on the capital of this pillar.

Plate 20. represents the west front of the Cathe-

Plates.

dral at Rheims, which has been long the boast of France, and in the excellence of its proportions, and the richness and delicacy of its ornaments, is regarded as the most perfect specimen of Gothic architecture in existence. This cathedral was originally founded in the year 818; it was burnt in 1210; occupied 30 years in rebuilding, and was finished in 1241; but it is supposed that the grand façade represented on the plate, was not completed till towards the end of the 13th century. The magnificence of the portal, and its nice proportion to the rest of the edifice, form the chief excellence and beauty of the west front, and fully display its characteristic features.

INDEX.

Index.

ARCHITRAVE is a term in architecture, denoting the lowest member of the entablature, or that part of it which rests immediately on the column.

ARCHON, from the Greek, signifying to *command* or *order*, is an appellation which was applied to the chief magistrate of Athens. Every person who aspired to the office of archon was required to prove that his progenitors had been citizens of Athens for three generations; that he believed and practised the religion of his country; that he had been obedient to his parents; and that he had served in the army. The commissioners appointed to enquire into these points being satisfied, an oath was administered to the archons, by which they bound themselves to maintain the laws under the sanction of forfeiting a statue of gold of the weight of their own body, which was to be presented to the temple at Delphi.

The whole administration of the state was entrusted to the archons, who were nine in number. The first was properly denominated Archon, because he was the chief of the nine. All domestic matters came under his jurisdiction, such as disputes between married persons, parents, and children, all causes relating to dowries, wills, and legacies, and providing tutors and guardians for orphans. To the second archon, who was called king, was committed the power of judging in all matters connected with religion. It was the proper office of the third archon to provide for the children of those who had fallen in defence of the country, to appoint games to commemorate the patriotism and valour of those who were slain in battle, to offer sacrifice to Mars and Diana, and to watch over the concerns of strangers in Athens. The othes six archons, who were entitled guardians of the laws, possessed functions of a more varied and general nature. All matters of police, which were not assigned to the three principal archons, fell under their jurisdiction.

ARCHYTAS, a Pythagorean philosopher, and the contemporary of Plato, flourished about 400 years before the Christian era; and by his influence with Dionysius the tyrant of Sicily, it is said he saved the life of his master Plato. His talents and conduct raised him seven times to the command of the army, in opposition to a positive law which prohibited the same person from holding that high office oftener than once; and he was frequently chosen chief magistrate of Tarentum his native city. Archytas was greatly distinguished for his mathematical knowledge; he discovered the duplication of the cube by means of the conic sections, and the method of finding two mean proportionals between two given lines; and to him also is ascribed the invention of the screw, the crane, and some hydraulic machines. Aristotle, it is said, is indebted to this philosopher for his methodical arrangement or general distribution of knowledge, entitled, the "Ten Categories." His skill in astronomy and geography is finely commemorated by Horace, who laments his fate in having perished by shipwreck on the Apulian shore. A treatise of Archytas, "On the Universe," and some fragments on "Wisdom," and on "the Good and Happy Man," are yet extant.

ARCOT, the capital of the Carnatic, in Hindostan, is a city of considerable extent, stands on the banks of the Paliar, and is strongly defended; and has been frequently a disputed post between the British on the one hand, and the native princes and the French on the other, from the time it was taken by Colonel Clive in 1751, till it finally became a tributary territory of Great Britain. Arcot is 55 miles south-west from Madras, and 65 north-west from Pondicherry.

ARCTIC, from the Greek, signifying a *bear*, is a geographical term synonymous with *northern*, as, *arctic* pole, *arctic* circle, which is $23\frac{1}{2}$ degrees from the pole, and *arctic* regions, which are included within that circle.

ARCTIUM, Burdock, a genus of plants belonging to the Syngenesia class.

ARCTOPUS, a genus of plants belonging to the Polygamia class.

ARCTOTIS, a genus of plants belonging to the Sygenesia class.

ARCTURUS, from the Greek, signifying the *tail* of the *bear*, is a fixed star of the first magnitude, in the constellation Bootes, towards which the tail of the great bear approaches.

ARCUEIL, a small town of France, and about three miles south from Paris, is celebrated for the excellence of its water, which is conveyed to Paris by a stupendous subterraneous aquæduct, 7000 toises in length, and constructed of free stone. This splendid work was executed in 1624, under the auspices of Mary of Medicis.

Arcueil has more lately acquired notice by the establishment of a society in 1806, which meets every fortnight at the country house of Berthollet, for the purpose of investigating physical and chemical subjects. Memoirs are read, experiments are repeated, and reports on journals and works connected with the objects of their researches, are drawn up by the members among whom this labour is distributed, and presented to the consideration of the society. The most distinguished philosophers of France are associates of this institution; and the volumes of their memoirs, already before the public, afford a favourable specimen of the importance of their labours.

ARDEA, including the stork, crane, and heron, is a genus of birds belonging to the order Grallæ. See Ornithology.

ARDEBIL, an ancient and celebrated town of the province of Aderbijan in Persia, stands in a wide plain on the banks of the river Karasu, not far from the Caspian sea, and is enclosed by a mountainous amphitheatre. Ardebil was once a royal residence, and a place of strength, but is now destitute of walls; the great square is spacious, and the caravanseray for the accommodation of merchants is a large building. All kinds of European and Asiatic manufactures are exposed to sale in the market place; and a constant intercourse is kept up, by means of caravans, with Constantinople and Smyrna. The tomb of a scheik, a reputed saint, in one of the churches, is regarded as an inviolable asylum, and attracts numerous pilgrims from all parts of Persia. Various fruits, as apples, pears, and peaches, are abundant in the surrounding districts, and the more elevated grounds afford excellent pasture to numerous flocks of sheep. Mineral waters abound, and the public baths of the city are supplied from copious springs nearly at the boiling temperature.

ARDECHE, a department of France, formerly the province of Vivarais, bounded on the north by the department of the Rhone and Loire, is more than 60 miles long, and from 15 to 30 miles broad, is watered by the Rhone, the Loire, and the Ardeche, and produces grain, wines, honey, and silk. The population exceeds 267,000, and Privas is the chief town.

ARDENNES, a department of France, including the great forest from which it derives its name, is bounded on the north by the department of Jemappe, and on the south by the department of the Marne, is well watered by the rivers Meuse and Aisne; abounds in all kinds of grain; coal, slate, and iron, are among its mineral productions; the extent exceeds a million of acres; and the population exceeds 264,000. Mezieres, which occupies an island formed by the Meuse, is the chief town.

AREA, the superficial content of any figure. Thus a square surface of twelve inches on each side contains 144 square inches.

ARECA, the Cabbage-tree, a genus of plants belonging to the class of Palms. The *Areca oleracae*, a native of the West Indies, and other warm climates, grows to a great height, and affords a delicate vegetable for the table.

ARENA, the central space of the Roman amphitheatre, in which the combats were exhibited. It was thus denominated because it was covered with sand; and hence, too, the gladiators were called *arenarii.*

ARENARIA, or Sandwort, a genus of plants belonging to the Decandria class.

AREOPAGUS, from the Greek, signifying the *hill* or *rock of Mars*, a sovereign tribunal at Athens, the justice and impartiality of whose decrees had acquired so high a character, that the gods themselves, it is said, were submissive to its decisions. The name and origin of this celebrated court are lost in obscurity. Conjecture assigns its institution to Solon, the great Athenian legislator; some derive its name from the suburbs of Athens, in which the hill or rock of Mars stood; and others trace it to the court of justice in which the senate assembled. Some are of opinion that the court of Areopagus existed before the time of Solon, and ascribe to that celebrated lawgiver the merit of reforming, restoring, and extending its authority, by uniting the power of other tribunals under its jurisdiction.

A law of Solon limited the privilege of being a a member of the Areopagus to those who had faithfully served the office of archon; and hence, by an obvious mistake, it has been supposed that the original number of the Areopagites corresponded with that of the archons. The number of members composing the court of the Areopagus seems to have varied at different periods of its history, from thirty-one to fifty-one, and even to five hundred. The character of those who were to be elected to the office was subjected to the severest scrutiny; the appointment of the judges was for life, and the fixed salaries were extremely moderate.

The whole affairs connected with the system of public police, and all matters relative to religion, fell under the jurisdiction of the court of the Areopagus. Their assemblies were held in the night, that their decisions might not be influenced by any other objects than by the arguments of the speakers. The parties themselves originally pled their own cause; but when greater refinement was introduced, hired pleaders were employed. To preserve impartiality, even the order in which causes were to be heard was regulated by lot. The decisions of the judges were given in the manner of the modern ballot. Two urns were employed to receive small pieces of flint, with which each judge voted. One of the urns was called the *urn of death* or *condemnation*, and the other was denominated the *urn of compassion* or *acquital.*

The simple edifice which was originally appropriated to the assembly of the Areopagus, was decorated and embellished about the time of Augustus. Seats of solid silver for the accuser and the accused, were introduced; and an altar dedicated to Minerva, and a tomb to the memory of Oedipus, were also erected. But the progress of luxury tainted the institution of the Areopagus with the corruptions and vices of the times; the severity of its regulations and decisions relaxed; it lost its original purity; and had altogether ceased to exist in the fifth century. The apostle Paul was called before this tribunal to give an account of his doctrine, and by his arguments and eloquence converted Dionysius one of its members.

AREQUIBA, a city of Peru, in South America, built by Pizarro in 1539, occupies a delightful spot in the valley of Quilca, and on the banks of the river Chili, and is 20 miles from the sea and 180 miles distant from Cusco. The climate is dry, temperate, and salubrious. The population, before an earthquake in 1785, exceeded 30,000; wine, oil, and corn are imported from Spain; and cotton-cloths and cordage, with other naval stores, are brought from Chili and Mexico. The houses, which are of stone, are constructed with neatness and elegance; a splendid bronze fountain adorns the great square; and a fine bridge affords a commodious communication to both sides of the river.

ARETIN, Guido, a native of Arezzo in Tuscany, flourished in the 11th century, and is known chiefly for his improvement in musical notation. He assumed the monastic habit, and was appointed abbot of a convent near his native place. The performance of a Latin hymn, the verses of which begin with the syllables, *ut*, *re*, *mi*, *fa*, *sol*, *la*, and the frequent repetition of the same sounds suggested the hint of adopting them in musical notation; the improvement was introduced; and the new discovery was considered of great importance in facilitating the method of learning the practice of the art. To the same author is ascribed the method of writing music on lines and spaces. Before his time a single line only was used, and the different notes were distinguished by the letters of the alphabet. Guido employed four lines with the intermediate spaces, after which another line was added, which completes the present system.

AREZZO, the ancient Aretium, a city of Tuscany in Italy, occupies the declivity of a hill which rises in the middle of a fertile plain, abounding in grain, wine, and oil, was a place of some trade in the time of the Romans, and was the birth place of Mæcenas, the great patron of literature in the Augustan age of Rome, and of the celebrated poet Petrarch.

ARGEMONE, Prickly Poppy, a genus of plants belonging to the Polyandria class.

ARGENTAN, a town in the department of Orne in France, stands on an eminence on the banks of the river Orne, contains a population exceeding 5000, and has some manufactures of lace and linen cloth, of light stuffs, and white leather.

ARGENTIERE, an island in the Grecian Archipelago, and the ancient *Cimolia*, from the earth so called, which is employed for washing, is about 18 miles in circumference, presents a sterile aspect of rocks, destitute of verdure, diversified with vallies, in which some vegetation appears, and produces some wheat, barley, and cotton. The only domestic animals that are reared in the island are hogs and poultry. The population is variously stated from 200 to 500; the women, remarkable for a stiff fantastic dress, are employed in knitting cotton stockings; and the men are engaged as fishermen and pilots. The calcined aspect of the rocks, the abundance of puzzolana, and the hot springs, are regarded by travellers as certain indications of volcanic action.

ARGENTON, a fine town in the department of Indre in France, occupies a delightful spot on the banks of the river Creuse, which flows through a fertile valley clothed with vineyards. The population exceeds 3000, and the manufacture of flint glass has been long successfully conducted.

ARGONAUTA, or Paper Nautilus, a genus of univalve shells, of which the most remarkable is the Argo, containing a singular animal, which has the power of raising itself to the surface of the ocean, and, with the aid of an apparatus resembling sails and oars, glides along the liquid element. To the movements of this animal the noble art of navigation has been fancifully traced. See Conchology.

ARGONAUTS, were illustrious Greeks, who according to the mythological history, embarked with Jason in the ship Argo from Colchis, to obtain possession of the golden fleece. Phryxus and Helle the son and daughter of Athamas, king of Thebes, to avoid the ill treatment of their stepmother, Ino, the daughter of Cadmus, went on board a ship which had a golden ram for an ensign, and sailed to Colchis. Helle was drowned during the voyage, in the strait which was called the *Hellespont*, or sea of Helle, now the Dardanelles. This is the account of the expedition as it is recorded by Greek writers. But the fabulous history represents Nephele, their divorced mother, bringing them a ram with a fleece of gold, and desiring them to mount on its back and direct their course to Colchis. With a rapid flight they were carried through the air, but Helle became giddy and fell into the Hellespont. Her brother arrived in safety at Colchis, offered the ram in sacrifice to Mars, and hung up the golden fleece in the temple of that divinity. Bulls breathing fire, and a dragon which never slept, guarded the fleece, to recover which was the object of the famous expedition undertaken by Jason and his companions.

The origin of this fable is ascribed by some to the method of collecting gold, which was washed down by torrents in the mountains of Colchis. Woollen fleeces were stretched across the stream to retain the particles, and the expedition was fitted out by the Greeks to procure that precious metal. According to Sir Isaac Newton, the Argonautic expedition took place about 30 years before the fall of Troy, and was an embassy sent by the Greeks to the nations along the Euxine and Mediterranean seas, to throw off the yoke of the sovereigns of Egypt, and the expedition of the golden fleece was merely a pretext to cover their real design. Dr Gillies, the historian of Greece, regards the fonndation of this celebrated expedition as a confederacy formed by the Grecian states, under the direction of the famous council, for the purpose of conquest and plunder; and supposes that the designs of the Argonauts were veiled under the allegorical expression *of carrying off the golden fleece*. Mr Bryant rejects the history of the Argonautic expedition as a Grecian fable, and refers the whole to traditionary stories connected with the deluge, and the preservation of Noah and his family in the ark.

ARGOPHYLLUM, White-leaf, a genus of plants belonging to the class Pentandria.

ARGOS, now ARGO, the ancient capital of Argolis, a district of Peloponnesus, was celebrated for the number and magnificence of its public edifices, of which few traces now remain; but it is still a place of considerable extent. An elegant mosque, rising from the shades of solemn cypress, presents a striking contrast to the whitened mud-built houses.

ARGUIM, or ARGUIN, an island on the western coast of Africa, is about 16 miles distant from Cape Blanco, and not more than two miles in length; but has been the scene of many hard struggles among different nations for its possession. It was discovered by the Portuguese in the 15th century, and the English, French, Dutch, and Portuguese became alternately masters of it during a period of more than 200 years. It seems to have been considered a convenient station for the gum trade; but it was probably from national jealousy and rivalship that its occupancy was so long and so expensively disputed.

ARGUS, according to ancient mythology, was the son of Aristor, and had a hundred eyes, fifty of which were always open. Argus was appointed by Juno to guard Io; but Jupiter sent Mercury, who by the powers of his flute charmed him to sleep, sealed up his eyes, and cut off his head. In reward for his faithful services, Juno transformed him into a peacock, whose tail has ever since exhibited a representation of his numerous eyes. This fable is the origin of the expression *Argus-eyed*, applied to those who are distinguished by vigilance and circumspection.

ARGYLESHIRE, an extensive county of Scotland, having the Atlantic ocean and the Irish sea on the west and south, the Frith of Clyde, Dumbarton, and Perthshires on the east, and Inverness-shire on the north, is about 115 miles long and about 70 miles broad, is intersected by numerous arms of the sea, and comprehends a number of the islands which come under the general denomination of the Hebrides. Exclusive of the islands, of which Islay, Jura, and Mull are the chief, included in this county, the main-land of Argyleshire presents great variety of picturesque and romantic scenery. Some of the mountains rise to an elevation of 3000 feet; the rivers, from their short course, are to be regarded only as mountain torrents; and Loch Awe is a beautiful expanse of water, 30 miles in length, and two and three in breadth. Ardnamurchan and Morven, towards the north, are peninsular districts, formed by arms of the sea stretching far inland; and Kintyre, the termination of which is at the Mull, or headland, projecting into the Irish sea, is united at Tarbet by a narrow neck of land. The Linnhe loch, which is to form part of the track of the Caledonian canal, traverses Argyleshire from north-east to south-west. The Crinan canal was planned and executed for the purpose of avoiding the circuitous and sometimes dangerous navigation round the Mull of Kintyre. It is about three miles long from Loch Gilp on the east to Loch Crinan on the west.

Mineralogy.—Argyleshire presents a wide and varied field for mineralogical research. Every kind of rock, whether of the primary or secondary class, is found within its limits. The Nuns islands, off the west coast of Mull, are composed of a beautiful red granite; gneiss is the repository of the lead-mines at Strontian; micaceous schistus forms a large proportion of the rocks in Islay and Jura; and the argillaceous schistus of Eisdale, Ballychelish, and other places on the western coast, furnish great quantities of excellent roof slate. The anomalous position of granular quartz, which occupies the place of granite in Islay and Jura, seems to subvert the venerated authority of certain modern geological systems. Syenite is abundant in some parts of Islay; and the beautiful porphyry of the same island is not inferior to the celebrated green porphyry of Egypt. Potstone, or Inveraray marble, as it is sometimes called, is dug out of a quarry at St Catharine's, on the banks of Loch Fine, which furnished the stone for the castellated mansion of the Duke of Argyle. The strata of limestone, both primitive and secondary, are extensive; examples of basaltic rocks, in a columnar, amorphous, or vertical form, are numerous, as in Mull, Staffa, and the neighbouring islands; and coal has been wrought for many years near Campbelltown; Great masses of breccia, or plumb-pudding rock, are deposited round Oban and other places; bog-iron ore covers tracts of considerable extent; and lead-ore has been long dug out in Islay and at Strontian.

Antiquities.—Numerous remains of ancient castles, the residence of powerful barons, yet exist in the main-land and islands of Argyleshire. The mouldering ruins of a seat of the chief of the Macdonalds, whose power enabled him to assume independent sovereignty, are yet visible in Islay; Castle-Dowart, on a projecting cliff in Mull, was the chief residence of the Macleans; and Dunstaffnage, near Oban, can boast of having been a royal residence.

Population, Towns, &c.—The population of Argyleshire, which in 1801 was not less than 78,000, had increased in 1811 to 85,585. It is divided into 49 parishes. Inveraray, Campbelltown, Oban, and Bowmore in Islay, are the chief towns. Many of the proprietors occupy elegant modern mansions; and Inveraray Castle, one of the residences of the Duke of Argyle, is also a modern edifice.

Husbandry, &c.—The chief cultivated crops of Argyleshire are oats, barley, and potatoes. Many of the recent improvements in agriculture have been successfully adopted by spirited individuals. The breed of cattle has greatly improved and extended, and is a very considerable source of revenue both to the islands and main-land; the dairy husbandry is pursued in some of the arable districts, and the mountainous pastures rear a numerous and hardy race of sheep. The real rent of the county in 1811 was about L.192,000.

Fisheries, Manufactures.—The great extent of coast, and the numerous bays and arms of the sea included in this county, afford great facilities for the fisheries, in which a large proportion of the inhabitants is profitably employed. Loch Fine has been long celebrated as a station for the herring fishery, which in the years 1794 and 1795 yielded a return of more than L.80,000. The manufactures are almost limited to those of a domestic nature. The manufactory of woollen established at Inveraray has not flourished, and attempts to introduce the manufacture of cotton have also failed. Iron is smelted at two places in the county, and tanning and ship-building are carried on at Campbelltown and Oban.

ARIADNE was the daughter of Minos, king of Crete, and, according to the mythological history, became enamoured of Theseus, who was sent to destroy the minotaur. Theseus having performed his task, and escaped from the labyrinth by means of a clue of thread with which she furnished him, married her, conducted her to Naxos, along with the Athenians whom he had relieved, and afterwards abandoned her. The fountain of Ariadne, in the isle of Naxos, is still an object of curiosity to the traveller.

ARIANO, a town of the farther principality of Naples, stands on the summit of a mountain, includes a population of 1400, has no trade or manufactures, and is subject to frequent earthquakes, one of which, in 1456, shook it to its foundations. It has never recovered from this disastrous calamity. The convent of Dominicans, in the vicinity of the town, has been three times thrown down, and as often rebuilt, within the period of a century. The most destructive shock which befel it happened in 1732, and spread devastation along the whole eastern range of the Appennines. The vine is cultivated in the surrounding country, and yields a pale sharp wine.

ARIANS, a religious sect, which derived its name from Arius, a presbyter of the church of Alexandria, who lived in the early part of the fourth century, and maintained that Jesus Christ was totally and essentially distinct from the Father; that he was the first of those beings whom God had created, and the instrument by whose subordinate operation all things were made, and therefore inferior to the Father in nature and dignity. The doctrine of Arius was condemned by the council of Nice which assembled in 325, the author himself was banished, and his books were ordered to be burnt. Recalled at the end of five years by the emperor, he drew up a confession of his faith, which proved satisfactory to the government, but Athanasius, bishop of Alexandria, refused to admit him and his followers to communion. The banishment of Athanasius was the consequence of this refusal. His successor in the church was equally obstinate; the peremptory order of the emperor was interposed, but before it was complied with Arius died, not without suspicion of having been poisoned.

For several centuries Arianism was either countenanced by the government, or suppressed by the civil power, as the influence of its professors or their opponents prevailed at the imperial court. Ancient writers, according to certain modifications of the doctrine, describe three classes of Arians, the *genuine Arians*, the *semi-Arians*, and the *Eunomians*. This doctrine continued to spread in different countries; it was supposed to be nearly extinct for some hundreds of years, when, as was alleged, it was restored by Erasmus, in his Commentaries on the New Testament; about the beginning of the sixteenth century it was encouraged and supported in Geneva, and afterwards in Poland; and in the beginning of the eighteenth century Mr Whiston, a divine of the church of England, and professor of mathematics in Cambridge, was deprived of the pastoral office, and of his professorship, for embracing Arianism. Dr Samuel Clarke adopted somewhat similar sentiments, and a keen and protracted controversy commenced, and was conducted with great ability on both sides. See *Mosheim's Church History*, and Collection of Pamphlets on the controversy concerning the Trinity, from 1712 to 1719, London, 1720, and Lardner's Credibility, vol. ix.

ARICA, a sea-port town of Peru, in South America, which has been often visited with severe earthquakes, is chiefly inhabited by Indians, blacks, and mulattoes; most of the houses are constructed of reeds or canes; has a little trade with some of the other towns on the coast; and in the valley, which stretches eastward into the country, cotton and pimento are cultivated. Rock-salt, dug from the contiguous mountains, is enumerated among the exports from Arica.

ARIES, the ram. See Ovis under MAMMALIA.

ARIES, one of the northern constellations, and the first of the twelve signs of the zodiac.

ARILLUS, the external covering of the seeds of plants, which is sufficiently conspicuous in the garden bean, the seeds of the cucumber, and still more obvions in coffee, as it includes two seeds or beans.

ARIMANIUS, the evil demon in the religious system of the ancient Persians. The Magi believed in the existence of two great powers in nature, the one the author of all good, and the other the author of all evil. Oromasdes, the name of the benevolent superintending power, dwelt in the purest light, formed man susceptible of virtue, and furnished him with the means of happiness, directed the revolution of the planets, controuled the elements, and preserved the order of the seasons; and for the accomplishment of his benevolent purposes, he created various subordinate deities. The abode of Arimanius, or the evil demon, was in the deepest darkness; he created a number of evil beings, to counteract, by their malignant influence, the good designs of Oromasdes, and to disturb the harmony both of the natural and moral world. But certain limits are set to his power, which in the end must yield to Oromasdes, when all evil shall be banished from the universe. The doctrine held by Zoroaster supposes that both these powers are subordinate to the first author of all things.

ARIMATHEA, the modern RAMLA, a town in Palestine, not far distant from Lydda, presents numerous remains of its former magnificence, but has now dwindled to a small place, with scarcely 1000 inhabitants, who are employed in the manfacture of soap and cotton.

ARION, a celebrated ancient musician and poet, was a native of Lesbos, and flourished about 600 years before the Christian era. He resided some time at the court of Periander king of Corinth, travelled into Italy, amassed great wealth, for the sake of which the sailors of the vessel in which he returned to Greece threw him into the sea; but a dolphin, which had been charmed by his melodious strains, took him on its back, and conveyed him safely on shore. Having escaped from a watery grave, he repaired to Corinth, and the king ordered the barbarity of the seamen to be punished by death.

ARIOSTO, Ludovico, a celebrated Italian poet, was a native of Reggio in Lombardy, where he was born in 1474; and his family, originally from Bologna, claimed alliance with the dukes of Ferrara; but could not boast of affluence equal to their illustrious descent. Destined by his father to the profession of the law, he spent five years at Padua, in the preliminary studies; but the pleasures of poetry allured him from the less attractive pursuits of legal disquisitions, and on the death of his father made him entirely abandon the preparatory steps for an employment which was little suited to the strong bias of his mind. His earliest years furnished ample proof of poetical genius in a dramatic composition, which he had wrought up from the beautiful story of Pyramus and Thisbe, in Ovid, and which was represented by the juvenile part of his father's family. When he relinquished the study of the law, he had acquired great facility in the composition of Latin poetry; he had been extremely assiduous in improving his own language; had cultivated Italian poetry; and even, it is supposed, had made some progress in his most celebrated production, the *Orlando Furioso*.

According to the fashion of the times, when princes encouraged the residence of men of literary distinction near their persons, that they might enjoy the reflected honour of their talents and reputation, Ariosto was admitted, in his 29th year, to the court of Hippolito, cardinal of Este, which was then the resort of some of the most learned men of the age; he was afterwards employed by the Duke of Ferrara in a diplomatic character, on a mission to the Roman pontiff; and when Leo X. his former friend, was raised to the pontificate, he revisited the ecclesiastical metropolis, in the expectation of improving his fortune, and obtaining the patronage of that distinguished pontiff. But the grant of a bull, securing to him the profits of his literary works, and the smiles of a gracious reception, were all the favours which he received from his holiness. Disappointment hastened his departure from the Vatican, and the festal scenes which were then exhibiting at Florence, drew him to that city, from which, after a residence of six months, he returned to the court of the cardinal of Este, resumed the composition of the Orlando Furioso, and, in 1515, published it at Ferrara, with a dedication to the cardinal, in a lofty strain of fulsome panegyric. But this flattery produced no applause from his patron, who reproved him for a misapplication of his time and talents in such a composition. Some time afterwards, Ariosto having declined an invitation to attend the cardinal in a journey to Hungary, his monthly salary was withdrawn, and he retired to a small house of his own in the vicinity of his native place. After the death of the cardinal he was invited by the duke of Ferrara to his court, and the liberality and beneficence of that prince enabled him to fix his residence in an agreeable situation in Ferrara, where he spent the remainder of his days, and composed great part of his works. He died in June 1533, in the 59th year of his age, and was interred in the church of St Benedict, without any memorial to mark the spot where his ashes reposed. After the lapse of forty years, a tomb, to which the bones of Ariosto were removed, was erected in one of the chapels of the church, by his friend Agostino Mosti, and on the tomb his statue was placed with a Latin inscription; and a great grandson of the poet, resolved not to be outdone by strangers, raised, in another chapel, a splendid marble monument with an alabaster statue.

Ariosto was the author of several other poetical compositions beside the Orlando Furioso, which has transmitted his name to posterity. The plan and many of the incidents of this poetical romance, are derived from the *Orlando Inamorato* of Boyardo, a poem of a similar character. The Orlando Furioso has been charged with being defective in unity of design; the plot is intricate and perplexed, and the train of events is broken and interrupted; but it is distinguished by remarkable fertility of invention, splendid imagery, and vigorous expression. But these striking beauties are not considered as sufficient to compensate for its faults, or to have its claim allowed before the tribunal of criticism to be ranked among the legitimate productions of the epic muse. The English reader has an opportunity of judging of its merits in *Hoole's Translation*.

ARISTÆUS was the son of Apollo and Cyrene, according to ancient mythology, and is said to have communicated to mankind some of the arts of husbandry and rural affairs; such as the cultivation of the olive, the curdling of milk, and the management of bees, and for these beneficial discoveries he was placed among the stars. The classical reader will find his name mentioned in the 4th Georgic of Virgil.

ARISTARCHUS, an eminent Greek philosopher, was a native of the island Samos, and flourished about 280 years before the Christian era. The studies of Aristarchus were particularly directed to astronomy. He revived the opinion of Pythagoras relative to the motion of the earth, for which it is said he incurred the charge of impiety. But his beautiful discovery is the method of finding the distance between the earth and sun; a problem which had long and unsuccessfully occupied the ingenuity of philosophers. When the dark and luminous parts of the face of the moon are equal, and separated by a straight line, he perceived that a line, drawn from the centers of the sun and moon, is at right angles to a line joining the centers of the earth and moon; and the centers of the earth and sun being joined by another line, a triangle is formed, the longest of whose sides denotes the distance of the earth from the sun, and the shortest represents the distance of the earth from the moon. The principle of the problem is correct, and its solution depends on accuracy of observation; for by measuring an arch of the heavens intercepted between the sun and moon, all the angles of the triangle are determined, and, consequently, the distance of the sun from the earth may be discovered in terms of the distance of the earth from the moon. Proceeding in this way, Aristarchus ascertained the distance of the sun from the earth to be about 18 or 20 times greater than the distance of the moon from the earth, or equal to 4,800,000 miles, which falls greatly short of the more accurate results of succeeding observers. But the error is properly laid to the account of the imperfection of the instruments with which the angles of the triangle were determined, rather than to any defect in the method itself. The invention of a sun-dial is also ascribed to Aristarchus. His *Treatise on the Magnitude and the Distance of the Sun and Moon*, was published at Oxford in 1687.

ARISTEA, a genus of plants belonging to the Triandria class.

ARISTIDA, Oat-Grass, a genus of plants belonging to the Triandria class.

ARISTIDES, a distinguished statesman and warrior of Greece, flourished at Athens about 500 years before the Christian era, and, from his noble patriotism and inflexible virtue, was honoured by his countrymen with the distinctive appellation of the Just. The life of Aristides seems to have exhibited a constant struggle with Themistocles, another powerful citizen, and also a warrior and statesmen; and as the influence of the rival citizens prevailed, and the public measures which they proposed were approved or rejected, the tribute of applause, or the vote of censure or condemnation was pronounced by the Athenians. The agitation excited in the state by these rival candidates for popularity, is said to have forced an acknowledgment from Aristides, that the affairs of the Athenians would never prosper till they were both thrown into a dungeon, or till their interference altogether ceased.

But whatever were the private animosities of Aristides, he was always foremost when the impending dangers of his country required his talents and services. His conduct and courage were highly conspicuous at the famous battle of Marathon, which was fought 490 years before the Christian era; soon after he was raised to the high rank of chief magistrate; by the influence of Themistocles, who preferred an accusation against him, he was banished from Athens; was recalled from exile on the threatened invasion of Greece by the Persians under Xerxes; displayed his usual skill and bravery at the famous naval engagement of Salamis; and his sagacity and prudence were not less remarkable in allaying the petty feuds which the rival interests of the different states of Greece excited and inflamed. But the distinguished stations which he held, and the eminent services which he performed to his country, left him only in possession of the gratifying honours of a patriot. Far advanced in age, he died about 467 years before the Christian era; the expence of his funeral was discharged by the public; his daughters were portioned from the treasury, and a pension and an estate were bestowed on his son.

ARISTIPPUS, an ancient philosopher, and the founder of the Cyrenaic school, which derives its name from Cyrene in Africa, the place of his nativity. The high reputation of Socrates drew him to Athens; but the pleasures of sense occupied a larger share of his attention than the pursuits of philosophy, and the wealth which he possessed furnished the means of unrestrained indulgence in all kinds of licentiousness and dissipation. But even these means were exhausted; and he was the first of the disciples of Socrates who derived any pecuniary emolument for public teaching. Driven from Athens by his dissolute manners, he visited Corinth; was shipwrecked in a voyage on the island of Rhodes; resided for some time at the magnificent and luxurious court of Dionysius, the tyrant of Sicily; and on his return to Cyrene, died at Lipara, one of the Æolian islands.

The philosophy of Aristippus corresponded partly with the doctrines of his master Socrates. He rejected the mode of instruction which was then pursued, and held logic to be quite sufficient to teach truth and to fix its bounds. Pleasure and pain, he maintained, were the motives which determined the actions of men; the former produces the softer emotions, and the latter excites the more violent passions. True happiness, he asserted, consists in the assemblage of pleasure, and the enjoyment of the present moment is the best way to attain it. Aristippus was the author of a history of Libya; dialogues; books on luxury; and some epistles.

ARISTOCRACY, from the Greek, signifying *chief* and *power*, is a form of government by which the supreme power is intrusted to the chief persons of a state, or the nobles.

ARISTOLOCHIA, Birth-Wort, a genus of plants belonging to the Gynandria class.

ARISTOPHANES, a celebrated Greek comic poet, who flourished in the time of Pericles, under whom the Athenians attained the highest degree of prosperity, and enjoyed the greatest importance among the states of Greece, and was cotemporary with Plato, Socrates, and Euripides. Of the private life of Aristophanes, little is known; and of the precise period of his birth or death no record is preserved.

Fifty dramatic productions are said to have been the offspring of the prolific muse of Aristophanes; but eleven only in a perfect state have survived the wrecks of time; and they must be always regarded as precious relics of antiquity, exhibiting a lively picture of the manners of the age, and a correct view of the structure and arrangement of the early Greek comedy. The unrestrained licentiousness which prevailed in dramatic writing when Aristophanes lived, exempted no character, however distinguished or respected by rank and virtue, from the most direct personal satire. The legislature interfered to check the growing evil, and enacted, that no individual should be exhibited on the stage by name. The effect of this regulation gave birth to the *middle* comedy of the Greeks, in which characters could only be introduced under fictitious names and marked allusions; but the indulgence was still abused, and demanded another prohibition, which was followed by the *new* comedy, in which the general follies of mankind are satirized by more delicacy of wit and more refinement of humour. Of the dramatic compositions of Aristophanes, ten are to be ranked with the *old* comedy; his *Plutus* is the only play which comes under the improved character of the *middle* comedy.

Numerous translations of the comedies of Aristophanes have appeared in different languages. But the *Plutus* and the *Clouds* seem to have been most frequently the subject of translation and critical discussion. A French version was executed by the celebrated Madame Dacier; and, by the labours of Mr Theobald, the English reader can peruse the same comedies in his own language; and he will find an excellent translation of the *Clouds*, in the *Observer*, by Mr Cumberland. In the same work an elaborate attempt is made to vindicate the Greek poet from the charge of having contributed to the condemnation of Socrates, by exposing his character in a ludicrous and unseemly manner on the stage.

ARISTOTELIA, a genus of plants belonging to the Dodecandria class.

ARISTOTLE, one of the most illustrious of the Greek philosophers, and founder of the Peripatetic sect, was born at Stagira, a city of Thrace, about 382 years before the Christian era. His father, Nicomachus, was the physician and friend of Amyntas, king of Macedon, and derived descent, as did also his mother, from Æsculapius, whose skill in the art of healing, displayed during the Argonautic expedition, had elevated him among the gods of antiquity.

At the age of 17, he repaired to Athens, induced apparently by his love of learning, of which it was the seat, and an anxiety to attend the lectures of the eloquent but mystical Plato, at that period its brightest ornament. His industry, acuteness, and capacity of intellect, soon obtained the admiration of that generous teacher, who had the good sense and the liberality not to demand any sacrifice of opinion from the student beyond the claims of satisfactory evidence, and to whom, it is no wonder, that the independent but grateful mind of Aristotle ever afterwards manifested the most amiable reverence and affection. Of the continuance and amount of this commendable respect, we have strong proofs, in spite of some malicious misrepresentations, in the verses which he wrote after the death of Plato, and the erection of altars in honour of his memory, though the appointment of his nephew Speusippus, as successor in the academy, a man of little talent and less virtue, might naturally enough have excited resentment, had there been any tendency to it, or at least have stifled the expression of regard, if not energetically springing from the sincerest conviction. It is quite conceivable, that an avowed difference of sentiment on certain abstract questions, had already originated a *new* school, and that consequently Plato could not with propriety consider Aristotle as the most suitable, though he might be the ablest person, to take the lead of his disciples.

Twenty years tuition, under this skilful and erudite man, furnished Aristotle with all the science and literature of his age, and qualified him for that singularly interesting office, which he discharged with so much glory—preceptor to the son of Philip of Macedon. Before engaging in this important charge, to which he was invited by a flattering letter from that sagacious monarch, with whom he preserved a hereditary friendship, Aristotle had married Pythias, the niece and adopted heiress of one of his old school-fellows, Hermias, the aspiring and unfortunate sovereign of Assus and Atarneus. This lady narrowly escaped the calamitous fate of her uncle, who fell a prey to the treachery of the ungrateful Mentor, by flying with Aristotle, to whom she was betrothed, from Atarneus to Mitylene, in the isle of Lesbos. Here she soon afterwards died, leaving Aristotle a daughter of the same name, who rewarded his conjugal and paternal virtues by the most affectionate tenderness and devotion.

Alexander was in his fourteenth year when our philosopher, scarcely recovered from the affliction, and now rather more than forty, commenced the superintendance of his education. For about eight years, in which this was continued, with characteristic enthusiasm on one side, and the highest excellencies of maturer judgment on the other, Aristotle augmented his consequence in the court of Philip by the advantages of his political counsel, and extended his fame among the Greeks in general, as well by friendly and successful interference in their behalf, as by the splendid fruits of his genius. Nor was he less fortunate with those who were immediately concerned in his peculiar responsibility. The honourable distinctions which Philip and his queen Olympias conferred on him, and the unequivocal demonstrations of Alexander's respect, were not more agreeable to his feelings than creditable to their own discernment and gratitude. What man could do, perhaps Aristotle really did—qualify but not subdue an ardour of mind, which already shadowed out the gigantic features of his future renown, and a spirit of enterprise which even the conquest of the world failed to exhaust. It is among the most striking proofs of Aristotle's superiority of character, that he was, it is believed, the only one of the hero's early acquaintances whom he continued to regard with undiminished attachment through all the seducing fortunes of his eventful career. This distinction, it is certain, was not purchased by mean compliances, or the neglect of painful, though necessary admonitions. The philosopher did not soften down the rigour of salutary principles in courtly subservience to any vicious inclinations; though it be equally true, that some of the rougher lineaments of the pupil scarcely lost any of their prominence under the corrective precepts of his authority and wisdom.

On the death of Philip, and the departure of Alexander for Asia, in prosecution of his ambitious designs, the philosopher, either averse to the expedition, or unfit, from his constitutional infirmities, for the difficulties with which it seemed pregnant, returned to Athens, where, indignant, as it has been said, at the pretensions or success of the slow-paced Xenocrates, the head of the academy, but more probably from zeal in the cause of learning, he commenced public teacher. Students soon flocked to him from all quarters. His lectures were delivered in the Lyceum, a place allotted by Pericles for military exercises, but the amenity and quietness of which peculiarly fitted it for a school of learning. The instructions of the philosopher were usually communicated while *walking* in the delightful shades of this retreat, and hence Aristotle obtained the title of Peripatetic, which descended to his disciples.

During the life of Alexander, whose confidence he preserved, and who liberally assisted him with materials for the improvement of science, Aristotle found it easy to defeat the insidious devices with which jealousy of his doctrines, or envy of his reputation, assailed him, under the garb of reverence for religion; but on the death of that prince, his enemies acquired such influence as to become daring in their opposition, and render his life both uncomfortable and insecure. He prepared a defence against their illiberal and unjust accusations; considering, however, the weakness of the best cause, when withstood by prejudice and malignity combined, as manifest in the fate of Socrates, he thought it more expedient to seek safety in flight than to trust to the armour of reason, being unwilling, as he jocosely observed, to give the Athenians another opportunity "of sinning against philosophy." His death, hurried, it is probable, by such unmerited treatment, happened about a twelvemonth after, in the place of his retreat, Chalcis, in Eubœa, when he was sixty-three years of age, and after having taught in the Lyceum twelve years. Herpylis, a second wife, Nicomachus, a son by her, and his daughter Pythias, bemoaned his loss. Theophrastus, to whom he bequeathed a valuable collection of books, and his own writings, which were very numerous, succeeded to the Lyceum. Aristotle's bodily appearance was a foil to his mental worth. He was short of stature; his limbs were out of proportion, slender and feeble; he had a kind of impediment in his speech, and his eyes were unusually small. It was sometimes imputed to him by the malicious and the ignorant, that he bestowed more care in decorating his person than it deserved, or than altogether became a philosopher; but the good sense of Aristotle justly appreciated the favourable impression of neatness in dress, and despised the silly affectation of indifference and carelessness.

The fate of Aristotle's works was somewhat singular. Few were published in his lifetime. The remainder, which had been committed to Theophrastus, passed, on his death, to Neleus, who consigned them again to his heirs, men ignorant of their value, and though anxious, yet injudicious in their preservation, depositing them in a vault under ground, where they remained unregarded and impairing for some generations. They were then sold to Apellicon of Athens, who expended much, but inadequate labour, on the execution of a legible and useful copy, which was seized on, as well as the whole library of the restorer, by Sylla, the conqueror of Athens, and transmitted to Rome. Tyrannion having procured the manuscript from Sylla's librarian, communicated it to Andronicus of Rhodes, a philosopher resident at Rome in the time of Cicero. By this man the task of arrangement and correction was skilfully accomplished, and henceforth copies, of various excellence indeed, multiplied throughout the Roman empire. The works being of different kinds and value, were not all equally regarded; and in consequence, besides the influence of many other causes, both common and particular, out of more than 400 treatises which Aristotle is said to have composed, not quite fifty survived the invention of printing. Those which embrace a wide sphere of important subjects, obscure as they were, from a sententious brevity peculiar to this profound thinker, and rendered often much more so by the mistakes and affected learning of his myriads of transcribers, translators, and commentators, were long appealed to as the standard of truth, from which all deviations partook of a danger little short of religious heresy. Lord Bacon broke in upon this ill-placed veneration, and summoned Aristotle himself to the bar of nature. The result has been a conviction of immense errors, but, at the same time, the establishment of a character for extent, variety, acuteness, and ingenuity of research, fertility of invention, and a general display of well organised judgment, which has perhaps never yet been surpassed by any individual since the mysteries of the world awakened genius in the breast of mankind. His treatises on *Rhetoric* and *Poetry* alone would immortalise his name; his *Ethics* and *Politics* abound in valuable observations; his *Logic* is ingenious, refined, and subtle, well calculated to exercise the faculties, though incapable of promoting science; his History of Animals exhibits most commendable diligence, and is precious as having both invited and facilitated the study of natural history. "The whole of his remains together, (says Dr Gillies, one of his most sensible annotators,) still form a golden stream of Greek erudition, exceeding four times the collective bulk of the Iliad and Odyssey."

ARITHMETIC is that science which investigates the properties of numbers; or, in its application to practical purposes, it is the art of calculation by means of numbers. See MATHEMATICS.

ARIUS, a divine of the 4th century, from whose peculiar doctrines the sect of the Arians derived their origin. See ARIANS.

ARK of NOAH, a large vessel which was constructed by the patriarch Noah, for the preservation of his family and the different species of living creatures during the universal deluge. Great diversity of opinion has prevailed among writers on this subject concerning the materials, form, capacity, time, and place of the construction of the ark. According to the Scripture account, the ark was built of *gopher* wood, and covered with pitch or some bituminous matter. The gopher is variously supposed to mean *cedar*, *cypress*, or *pine*, which, from their resinous nature, are less subject than other woods to rot or decay. The *form* of the ark was an oblong square, the roof sloping and the bottom flat. As its object was to float on the waters of the deluge, no mention is made of any apparatus fitted for the purpose of impelling or guiding it. Three separate stories have been assigned to the ark; the lowest for the beasts, the middle for food, and the uppermost for the family of Noah and the feathered tribes; the whole is divided by some into 72 apartments, while others, more fertile in conjecture, reckon not fewer than 400 separate rooms. The capacity of the ark is described by Moses to be 300 cubits in length, 50 in breadth, and 30 cubits in height; but the dimensions are vaguely conjectured, from the indeterminate length of the cubit. Some determine the length of the ark to be 550 feet, others 450 feet, and the breadth and height in proportion. According to the first dimensions, the cubit is calculated at nearly 22 inches, and, according to the last, at rather less than 18 inches. Of the *time* of the construction of the ark, it is most generally supposed that the building commenced in 1536 and was completed in 1656 from the creation of the world, and including a period of 120 years. The *place* assigned for its construction has been variously represented by different writers, as Palestine, Mount Caucasus on the borders of India, some part of China, and the country of Babylon in Chaldea.

ARKWRIGHT, Sir Richard, a celebrated manufacturer, who, by his ingenuity in the invention of cotton-spinning machinery, raised himself from a humble station in life to rank and opulence. About the year 1767, after he had relinquished the trade of a barber, which was his original employment, he made a visit to Warrington; and being occupied with the long sought for discovery of the perpetual motion, he applied to Mr Kay, clock-maker of that place, to construct a piece of machinery with this view. From Kay, it is said, he derived the first hint of directing his mechanical invention to the more profitable construction of a machine for spinning cotton, and such a machine Kay described to him. By their united efforts the machinery was completed; Arkwright obtained a patent in 1769, renewed it in 1775, but it was set aside ten years afterwards; and having entered into partnership with Mr Smalley of Preston, the business commenced. But being unsuccessful, they removed to Nottingham, assumed wealthy partners, and erected a large cotton-mill, which was driven by horses.

The machinery was still farther improved, establishments on a larger scale were formed, the business spread throughout the kingdom, and 20 years had scarcely elapsed, when it assumed a magnitude and importance, whether the amount of capital or the number of persons employed, or its value as a great national concern be considered, which far exceeded all the estimates of the most sanguine speculation. By the spirited exertions of the late Mr Dale of Glasgow, the cotton-spinning trade was early introduced into Scotland, and soon became a formidable rival to the parent establishments.

A claim in favour of Mr Kay, as the original inventor of this wonderful machinery, has been advanced; but as the share which that ingenious mechanic had in the invention and prosecution of the improvement is not specified, the merit to which he is justly entitled cannot now be ascertained. His name is never associated with those who were concerned in the progress of the discovery, although the omission is not to be regarded as positive evidence that he had no right to its honours and emoluments.

In the year 1786, Mr Arkwright, whose name was now well known in every part of the kingdom, and whose ingenuity was rewarded with the possession of great wealth, was appointed by the high sheriff and Hundred of Wirksworth to present an address to the king, and on that occasion he received the honours of knighthood. He died in August 1792 at his works at Crumford, in Derbyshire.

ARLES, a city in the department of the Mouths of the Rhone, in France; stands on the declivity of a hill on the eastern bank of that river, and in the midst of a rich and fertile country, although in some places covered with marshes, and includes about 18,000 inhabitants. This city had risen to great celebrity in the time of Julius Cæsar, and it still exhibits numerous splendid remains of Roman antiquities in the ruins of two temples, a triumphal arch, and an amphitheatre, 400 yards in circumference, and above 100 feet in height. A granite obelisk, 58 feet high and 7 feet diameter at the base, supposed to have been brought from Egypt by the Romans, was dug up in a garden in 1675, was adorned with the arms of France, and dedicated to Louis XIV. A fine statue of Diana, discovered in 1651 among the ruins of the amphitheatre, adorns the gallery at Versailles.

ARMADA, an appellation used by the Spaniards to denote a fleet of men of war, but it is commonly restricted to the immense armament which was fitted out by Philip II. for the invasion and conquest of England. This armada, on which the Spaniards, with no small degree of confident presumption, bestowed the title of *Invincible*, was composed of 150 ships, most of which were superior in strength and magnitude to any which had before been constructed, navigated by 8000 sailors, and having 20,000 veteran troops, beside 2000 volunteers, many of them from the first families in Spain, on board. The number of great guns amounted to 2650, beside a copious supply of military stores. The fleet was provisioned for six months. The resources of England seemed to offer but a feeble opposition to this immense force, but the deficiency of means was well supplied by caution and prudence. All ranks vied with each other in equipping ships to strengthen the naval armament of the nation, and all capable of bearing arms flocked to the shores of the channel. Queen Elizabeth herself was seen in the camp at Tilbury, encouraging her troops, and, by her cheerful and undaunted manner, contributed much to rouse the drooping spirits of the kingdom.

The armada was ready to sail from Lisbon, the place of rendezvous, in May 1588; but the death of the commander, and a storm after leaving port, which required it to return for repairs, caused delay. At last it appeared in the English channel. Sir Francis Drake, the admiral of the English fleet, annoyed it greatly by his lighter and more manageable ships. Two large ships of the Spaniards, one of which took fire, and the other sprung her mast, were outsailed by their own fleet, and fell into the hands of the English, with very considerable treasure. The armada anchored off Calais; the English fitted up eight small vessels as fire-ships, and sent them among the enemy in the night. This destructive stratagem produced great disorder; the Spaniards cut their cables, and fled in the utmost precipitation; the English attacked them next morning; and beside dispersing the fleet, took or destroyed twelve of their large ships. No farther offensive operations could be attempted; the object of the Spanish commanders was now to retreat homewards; but contrary winds forced them to undertake the circuitous voyage by the north of Scotland. Many of the ships were wrecked on the coasts of Scotland and Ireland; and such was the disastrous issue of this remarkable expedition, that not more than half of the ships and men which sailed in it ever returned.

ARMADILLO, from the Spanish, signifying *armed*, the appellation of a tribe of quadrupeds which is furnished with a testaceous covering like a coat of mail. See *Dasypus*, under MAMMALIA.

ARMAGH, a county of the province of Ulster in Ireland, bounded by Lough Neagh on the north, Tyrone and Monaghan on the west, Louth on the south, and Down on the east, stretching from north to south about 32 miles, and about 20 miles in breadth, and including an area which is estimated at more than 450 square miles. The face of this county is finely diversified with gently rising hills, and in many places the soil is rich and fertile; but the mountainous district, called the Fews, presents a rugged and barren aspect, and is chiefly occupied as pasture land. The farms are in general of small size, and the improvements in agriculture are gradually adopted. Corn, flax, and potatoes are the chief crops.

The Blackwater, which is partly navigable, and divides the county from Tyrone, is one of the principal rivers; and Lough Neagh, which is 15 miles long and seven miles broad, receives the waters of seven rivers, and has only one outlet, the Ban, to the north, and the banks of which are partly flat and marshy, and partly rocky and precipitous, is the principal lake connected with the county. Strata of limestone are abundant in Armagh, and marble of a beautiful appearance is sometimes dug out. Some indications of lead ore and other metals have appeared, but have not been prosecuted.

Armagh, the metropolitan see, is the largest province of Ireland, and includes ten dioceses. The population is estimated at 130,000. The inhabitants of the mountainous districts are chiefly Roman catholics; the protestants amount to one-third of the whole population, and of this class the presbyterians form the largest proportion. The linen manufacture in its various branches affords extensive employment to the inhabitants of Armagh, and its annual average value has been estimated at L.300,000.

ARMAGH, the capital of the county of the same name in Ireland, is said to have been the seat of a university soon after the establishment of Christianity, and in the 12th century was constituted by the Pope's legate the metropolitan see. The primacy is reputed to be worth L.8000 annually. The palace of the archbishop is a fine edifice; and the schoolhouse, which adds to the beauty of the place, is richly endowed. The linen market of Armagh is one of the most extensive in the province; and the banks of the Callen, near the town, are covered with bleaching grounds. Armagh is 62 miles from Dublin.

ARMENIA, a country of Asia, having the Euphrates as its boundary on the west, Diarbekir on the south, Persia on the east, and Georgia on the north, and exhibiting a varied aspect of bleak mountains and fertile vallies. The elevated districts afford pasture to numerous herds and flocks; and the fertile soil of the low lands, in a temperate climate, yields abundance of corn, wine, and excellent fruits. In some places tobacco is extensively cultivated. The mountainous regions are subject to severe cold; and the droughts in summer require the husbandman to have recourse to frequent irrigation. Rock salt is dug from quarries, and, beside what is consumed in the country, is transported on the backs of buffaloes to Persia.

Christianity was early established in Armenia. The church establishment is composed of patriarchs, archbishops, doctors, secular priests, and monks. They have seven sacraments, and at certain seasons subject themselves to rigid abstinence and frequent fastings. The Turkish inhabitants of Armenia profess the Mahometan faith. The manufacture of tapestry and of silk and woollen stuffs is successfully conducted in various districts; and the mercantile enterprise of the Armenians is celebrated throughout every part of the civilized world. Erzerum is the capital.

The history of Armenia refers to the conquest of their country by the Assyrians, the Medes, and the Macedonians. Two prefects under Antiochus the Great threw off their dependence, assumed regal power, and divided the country into Armenia Major and Minor, a division which remains to the present day. An alliance with the Romans strengthened their authority, and secured them in their possession. The Armenians maintained a vigorous struggle with the Romans, but were at last defeated with great slaughter by Lucullus their famous general; they were afterwards governed by their own kings, but in the character of allies or tributaries to Rome, and in the time of Trajan were reduced to the form of a Roman province. Restored to the appearance of independence, Armenia could again boast of being ruled by its own sovereigns, who performed homage to Constantine the Great. But in the time of Justinian II. it was conquered by the Saracens, and held under their dominion till the irruption of the Turks, who changed the name to Turcomania. The invasion of Persia by the Turks drew off their forces, and afforded the Armenians an opportunity of resuming their independence, which they retained till the Tartars made themselves masters of their territory. The ancient kings seem to have been restored; for, in 1472, a sovereign of Armenia succeeded to the crown of Persia, and annexed his native dominions as a province to that empire. But, in 1522, Armenia was finally subdued by Selim II. and excepting some part of the eastern territory, which is claimed by Persia, has continued to the present day subject to the Ottoman Porte.

ARMILLARY, in its general signification, is applied to something composed of rings or circles; as the *armillary* sphere, which consists of a number of circles representing the imaginary divisions of the world, and so arranged as to aid the conception in studying the motions and relative positions of the heavenly bodies.

ARMINIANISM, the peculiar doctrines which were held by Arminius, a protestant divine, and a native of Holland, who was born in 1560, settled as a minister in Amsterdam in 1588, and about the beginning of the 17th century was appointed professor of divinity at Leyden. He was greatly distinguished for the integrity of his character, and the extent of his learning. He died in 1609. Arminius was engaged by Martin Lydias, professor of divinity at Franeker, to refute the opinions of certain clergymen at Delft, concerning predestination; but in the progress of the investigation he not only adopted the doctrine which he had undertaken to oppose, but carried it still farther; and thus originated the opinions which bear his name.

The peculiar tenets of the Arminians refer to predestination, universal redemption, the corruption of man, conversion, and perseverance. 1. On the first point it is maintained, "That God, from all eternity, determined to bestow salvation on those who he foresaw would persevere unto the end in their faith in Jesus Christ, and to inflict everlasting punishment on those who should continue in their unbelief, and resist unto the end his divine succours; so that election was conditional, and reprobation in like manner the result of foreseen infidelity and persevering wickedness.

2. On the subject of universal redemption, they held, "that Jesus Christ, by his sufferings and death, made an atonement for the sins of all mankind in general, and of every individual in particular; that, however, none but those who believe in him can be partakers of their divine benefit."

3. With regard to the corruption of man, the Arminians taught, "that true faith cannot proceed from the exercise of our natural faculties and powers, nor from the force and operation of free-will, since man, in consequence of his natural corruption, is incapable either of thinking or doing any good thing; and that therefore it is necessary, in order to his conversion and salvation, that he be regenerated and renewed by the operation of the Holy Ghost, which is the gift of God through Jesus Christ."

4. The doctrine of conversion maintained by the Arminians is, "that this divine grace, or energy of the Holy Ghost, begins and perfects every thing that can be called good in man, and consequently all good works are to be attributed to God alone; that, nevertheless, this grace is offered to all, and does not force men to act against their inclination, but may be resisted and rendered ineffectual by the perverse will of the impenitent sinner."

5. On perseverance, they held the opinion, "that God gives to the truly faithful, who are regenerated by his grace, the means of preserving themselves in this state." The first Arminians expressed some doubts of this doctrine, but their followers maintain, "that the regenerate may lose true justifying faith, forfeit their state of grace, and die in their sins."

Arminius promulgated his opinions when he was professor of divinity at Leyden. The controversy with the Calvinists, to whose doctrines they were opposed, became more general and more violent after his death, and at one time threatened the country with the calamities of civil war. The synod of Dort, which was assembled by orders of the states-general, and was composed of delegates, not only from the United Provinces, but from the reformed churches of Switzerland, Germany, and England,—condemned the followers of Arminius unheard, and declared them to be guilty of pestilential errors, and corrupters of true religion. This decision subjected those who were charged with Arminianism to severe persecution; they were stript of their employments; the clergy were silenced, and their congregations were suppressed. But on the death of Prince Maurice, in 1625, who had keenly espoused the Calvinistic side of the question, they were fully restored to their former privileges; and, under the toleration of the legislature, they erected churches, and established a college at Amsterdam.

ARMONIAC, or sal armoniac, the old name for sal ammoniac, or muriate of ammonia. See CHEMISTRY.

ARMOUR, a defensive habit, which was formerly employed to cover and protect the body from the attacks of an enemy. A complete suit of armour was composed of the casque or helmet, gorget, cuirass, gauntlet, tasses, brassets, cuisses, and covers for the legs, to which the spurs were attached. This furniture was denominated *armour cap-a-pee*, or from head to foot, because the whole body was covered with it, and it was worn by cavaliers and men-at-arms. The head-piece, the cuirass, and tasses only, and of a lighter construction, were worn by the infantry. But defensive armour is entirely laid aside in the modern warfare of civilized nations, with the solitary exception of the cuirass, which was worn by Bonaparte's Imperial Guard at the memorable battle of Waterloo; but it seems to have formed a feeble defence against the powerful onsets and dauntless intrepidity of their brave opponents, who trusted only to their offensive weapons, to which the result of that battle, and the numerous cuirasses which have reached this country, and have become a kind of mercantile commodity, bear ample testimony. While defensive armour was in use, its various parts were constructed of different materials in different nations and in different periods of society. See Grose *on Ancient Armour*.

ARMS is a general appellation for all kinds of weapons, whether of an offensive or defensive nature. The various offensive weapons, which were formerly in use among civilized nations, have given place to the sword and to fire-arms.

Arms or armories are marks of dignity and honour, composed of certain figures and colours, authorised by the sovereign, and borne on banners, shields, coats, and hence they are called coats-of-arms, for the distinction of persons, families, and states. See HERALDRY.

ARMSTRONG, JOHN, a physician, poet, and miscellaneous writer, was born about the year 1709, in Castleton parish in Roxburghshire, in Scotland, where his father was clergyman; studied at the University of Edinburgh, and was admitted to a medical degree in 1732; and soon after settled in London, where it is supposed he supported himself by his literary talents. In 1735, he published a humorous essay on the empirical practice which then prevailed in the metropolis. A medical work appeared in 1737, which was soon after followed by the *Economy of Love*, a licentious production, which, whatever be its poetical merit, is not very creditable to the feelings of the author; but a corrected edition, which was published after an interval of several years, shewed that he was not insensible of its hurtful tendency.

In 1744, the public were gratified with the best production of his muse, *The Art of preserving Health*, a poem which still enjoys a high degree of celebrity, and is regarded as equal to any other of a didactic character in modern times; and although it has been perhaps justly charged with too frequent allusions to classical antiquity, it is to the excellence of this poem that Armstrong is indebted for having his name associated with the votaries of the British muse. His poems on *Benevolence*, and on *Taste*; the *Forced Marriage*, a tragedy; *Sketches on various Subjects*, under a fictitious name; a volume of *Medical Cases*, with some miscellaneous and fugitive pieces,—make up the list of Dr Armstrong's literary productions, but add little to his fame.

Dr Armstrong accompanied the army in Germany as physician in 1760, and made another visit to the continent at a later period of his life. His medical practice seems to have been extremely limited; and his want of success is ascribed by himself or his friends to a deficiency in those winning arts and prepossessing manners which are oftener better fitted to ensure popularity than more solid but less obtrusive talents. But the indolence of his character, and the literary retirement which he loved, are supposed to have been the chief causes of his failure. He died in 1779.

ARNE, Thomas Augustine, an eminent musical composer, was born in London in 1710. During his residence at Eton, his strong predilection for music began to appear, and became so powerful, that, on his return to his father's house, he concealed an instrument in his apartment, and muffled the strings with a handkerchief, that the sounds might not be heard by the family. Destined by his father for the profession of an attorney, the irresistible bent of his inclination was ill suited to the plodding application which it required, and he was at last permitted to pursue his favourite studies as the business of his life. Dr Arne was first known to the public as leader of the band at Drury-lane Theatre; and his first musical composition, which was for Addison's opera of Rosamond, was successfully performed in 1733. Beside numerous pieces of a lighter description, as ballads, duets, and trios, which were performed at Vauxhall, the music which he composed for Fielding's burletta of *Tom Thumb*, the *Comus* of Milton, the opera of *Artaxerxes*, translated from the Italian of Metastasio, and Mallet's *Masque of Alfred*, in which the popular song of Rule Britannia first appeared, added to the celebrity, and extended the fame of the author. As a composer of oratorios, and in some musical entertainments, in which he furnished both the poetry and music, he was less successful. He received the degree of Doctor of Music from the university of Oxford, and he died in 1778.

ARNE, a river of Switzerland which derives its origin from the Alps, falls into the Rhone near Geneva, by its greater velocity preserves its own current for some miles distinct from the more placid stream of the Rhone.

ARNHEIM, the capital of Lower Guelderland, and formerly one of the Hanse towns, stands on the right bank of the Rhine, near its junction with the river Yssel, is strongly fortified with ramparts, as well as with a deep ditch on one side and the Rhine on the other. The walls are adorned with rows of trees; the streets are regular; and many of the houses are not deficient in elegance. The population is stated at 15,000; and the navigation of the Rhine, and artificial canals, afford numerous facilities to commercial activity.

ARNICA, Leopard's Bane, a genus of plants belonging to the Sygenesia class. *Arnica montana*, a native of Germany, was once in some repute in paralytic and feverish disorders; but its effects were probably overrated.

ARNO, the ancient Arnus, a river of Italy, which has its source in the Appenines, passes through Florence and Pisa, and falls into the Tuscan sea eight miles below the latter town.

ARNOLD, Samuel, an eminent musical composer, was born in 1739, was a pupil in the chapel-royal, St James's, London; was first known to the public by the beautiful and admired air, *If 'tis joy to wound a lover*; was appointed musical composer to Covent-garden Theatre in 1760; he was preferred to the same situation in the Hay-market Theatre in 1776; in a few years afterwards succeeded to the place of organist and composer to the royal chapel at St James's; and in 1796 was chosen director of the annual festival at St Paul's before the sons of the clergy. The university of Oxford conferred the degree of Doctor of Music on Mr Arnold on the installation of a chancellor, when he presided at the performance of the oratorio of the *Prodigal Son*, which is his own composition. The death of this celebrated composer happened in 1802.

The *Cure of Saul*, which was set to music in 1767, the oratorios of *Abimelech*, the *Resurrection*, and the *Prodigal Son*, and the popular performances of the *Maid of the Mill*, *Inkle and Yarico*, the *Agreeable Surprise*, the *Surrender of Calais*, *Peeping Tom*, and the *Shunamite Woman*, afford ample proof of the musical genius of Dr Arnold. He published four volumes of cathedral music, and superintended an edition of the works of Handel.

ARNOTTO, a dye-stuff, in the form of a hard paste, obtained from the seeds of *Bixa orellana*; for the mode of preparing which, See Annotto.

AROMATICS are such vegetable substances as have a fragrant penetrating odour, and a warm pungent taste. as ginger, pimento or Jamaica pepper, and caraway seeds.

ARPINO, the ancient Arpinum, a town of the Neapolitan territory, and celebrated as the birth-place of Caius Marius and Cicero. It is curious to remark that the family seats of these two renowned characters of antiquity are both occupied by monastic establishments.

ARRACAN, a country or province of Asia, and also the capital of the province. See Aracan.

ARRACK, or Arack, a spiritous liquor obtained from the fermented juice of different vegetable substances, as the tops of the cocoa-nut and other trees of the palm kind, from rice, and the liquid which flows from an incision or cut branch of the palm trees.

ARRAGON, a province of Spain, having the Pyrenees on the north, Catalonia and Valencia on the east, New Castile on the south, and part of Navarre on the west, about 240 miles in length, and 160 in breadth, and greatly diversified in its aspect with lofty mountains, barren plains, and fertile vallies. The climate is in general temperate, but the higher regions are subject to severe tempests. The Ebro, Cinca, Segra, and Arragon, are the chief rivers.

Natural History.—Arragon has been celebrated for its mineral productions from the time of the Romans. Copper ore is dug out in some places; indications of gold and silver have been observed; cobalt was discovered in the beginning of the 18th century, and wrought for more than 50 years, and the iron of this province is esteemed of a superior quality for sword-blades; marble, gypsum, jet, and rock-salt are abundant; and aluminous schistus affords a rich and pure material for the manufacture of alum. Extensive tracts are covered with Spanish oak, the most stately of the vegetable tribe in the province; the hills are clothed with pines, and numerous plants of humbler growth, as juniper, *cistus*, or rock-rose, and *arbutus uva ursi*, or trailing arbutus, adorn the heathy moors, or conceal the sterile aspect of the bare rock from the eye of the traveller. The bear and the wolf have their abode still in the mountainous recesses of Arragon; the lynx and the ermine are natives of the more elevated regions; and the stag, the ibex, and different species of the goat tribe are abundant. The sheep is the most important of its domestic animals. In the commencement of the 18th century, the stock of sheep in Arragon was estimated at a million and a-half. Beside numerous species of the feathered race, the vulture is common; and the golden eagle and the ptarmigan frequent the Pyrenees. The scorpion is a native of Arragon; and the ravages of the locust have oftener than once been followed by famine and pestilence.

Population, &c.—The population of Arragon, in 1788, exceeded 623,000, in which are included 10,000 priests and others, male and female, connected with religious institutions, and 9000 persons of the order of nobility. But extensive tracts of country are still altogether destitute of human habitations. Beside wool and silk, wheat, hemp, flax, saffron, and wine are enumerated among the productions of the more fertile districts. But husbandry is yet in a rude and imperfect state. The woollen manufactures once flourished, but are now less prosperous. Soap, glass, earthen-ware, gunpowder, and leather, are still the objects of industry to many of the inhabitants in different places of the province. Wheat, hemp, and wool, with woollen stuffs, silk, and stockings, are the only exports from Arragon. Saragossa, the capital, which, on account of its memorable siege during the invasion of the French in the beginning of the 19th century, must hold a conspicuous place in the annals of Europe, Alcarazin, Calayatud, Daroca, and Jacca, are the chief towns.

ARRAGONITE, a singular mineral production of Arragon, from which the name is derived, and which, on account of its form and hardness, has occupied much of the attention of mineralogists and chemists. See MINERALOGY.

ARRAIGNMENT is a law term, which signifies that part of a judicial process in which a person charged with a crime is called to the bar of a competent tribunal to answer an indictment. See Blackstone's *Commentaries.*

ARRAN, an island on the western coast of Scotland, about 22 miles long and nine or ten miles broad, presenting in the northern division a rugged surface of lofty mountains, and towards the south flat land of considerable extent fit for arable culture. Goatfield, rising to an elevation of 3000 feet above the level of the sea, rewards the fatigue of the traveller in the ascent, with a wide, varied, and rich prospect. Lamlash bay on the east side, and protected by an island of the same name, is one of the safest and most commodious harbours in the kingdom, and is capable of receiving a numerous fleet of ships of large burden.

Mineralogy.—Arran, including within a small compass, both primary and secondary rocks, presents a fine field of investigation to the geologist. The more elevated and central parts of the northern division of the island are chiefly composed of grey granite, in the cavities of which crystals of smoky quartz and crystallized feldspar are sometimes formed. Slaty or schistose granite or gneiss, micaceous and argillaceous schistus, appear in the lower regions. In the southern division of the island, red sandstone is the prevailing rock; and sandstone, limestone, bituminous shale, and a small deposition of blind coal, are met with on the north-eastern shore. Arran is the most copious repository of pitchstone which has been yet discovered. Thick veins of this mineral traverse the sandstone rocks. Small crystals of pistazite, a rare mineral in this country, line the fissures of the argillaceous schistus. Splendid masses of schistose porphyry, or clinkstone of a columnar form, appear in the lofty and precipitous cliffs of Lamlash island. The small island of Pladda, near the southern extremity, and on which a light-house is erected, consists chiefly of a similar rock. In some parts of Arran, other porphyritic rocks and basalt are not uncommon. The spacious caves in the sandstone on the west-side of the island, are usually visited by travellers as objects of curiosity.

Population, &c.—The greater part of Arran is the property of the Duke of Hamilton; two farms belong to the Marquis of Bute; and the family of Fullerton has held possession of a small estate for many centuries. The population of Arran is probably between 6000 and 7000. In 1798 it was estimated at 5800; and the population of the whole county, which includes Bute and some smaller islands, exceeds 12,000. The whole island is divided into two parishes. The only village is Lamlash, on the shore of the bay of that name. Agriculture, which is advancing in improvement, the fisheries, which are profitable, and the ordinary domestic manufactures, are the chief occupations of the inhabitants. Oats, barley, and potatoes are the principal crops; black cattle and some horses, with a little kelp made on the shores, are exported. The gross rent, stated a few years ago at L.5500, has no doubt increased with the progressive improvement of the soil and mode of husbandry. Numerous flocks of sheep and goats are reared in the elevated pastures. Various species of the genus *tetrao* are found in Arran. The black cock frequents the coppices; the partridge is common in the corn land; grouse abound in the heathy moors; and the ptarmigan select the loftier regions of the mountains for their retired abode.

Antiquities.—Numerous fragments of druidical remains are seen in different places of Arran. Ranza castle, now a ruin, near the north end of the island, from its massy appearance, seems to have been a place of considerable strength, and is said to have been once a royal residence. Brodwick castle, on a precipitous cliff not far from the eastern shore, is an old castellated structure, but of a less ancient period, and is the occasional residence of some part of the family of the chief proprietor.

ARRAS, the *Attrebatæ* of Cæsar, was formerly the capital of Artois, and is now the chief town of Pas-de-Calais in France; occupies an elevated situation near the river Scarpe, and is divided into two parts by a narrow valley, which is watered by a small stream. Arras is strongly fortified, and is adorned with many fine buildings. The cathedral is a grand edifice, in the Gothic style, and surmounted by a lofty tower. The brazen pulpit of another church, which is in the form of a tree, supported by two bears, is an object of singular curiosity. The population of Arras is estimated at 20,000. The manufactures of linen and woollen, which were formerly prosperous, declined during the revolution, and a porcelain manufactory shared the same fate. *Arras* hangings, a kind of tapestry, which, it is supposed, was first made in this place, derived its name from the town. Arras is 130 miles north from Paris, and 27 miles north-west from Cambray.

ARREST, is a law term, denoting the restraint of a man's person, for the purpose of enforcing his obedience to the law, and it is executed either in civil or criminal cases. See Blackstone's *Commentaries.*

ARRESTMENT, a term in the law of Scotland, which signifies the securing of the person of a criminal, or, in a more general sense, denotes the diligence by which a creditor detains the goods of a debtor in the hands of a third party till the debt be liquidated. See Bell's *Dictionary of the Law of Scotland.*

ARRIAN, a Greek historian, who was a native of Nicomedia, in Bithynia, and flourished at Rome under Adrian and the Antonines, in the second century. His talents and conduct raised him to high official situations, both in a civil and military capacity, and even, it is said, to consular dignity. Arrian was the author of numerous historical works, all of which have perished among the wrecks of time, excepting the history of the *Expedition of Alexander the Great,* a production which has been always respected for the accuracy and truth of the narrative, and which is not less admired for the elegance of its style, the correctness and purity of which are rarely surpassed in the classical ages of Greek literature. Arrian was the the disciple of Epictetus, and his learning and eloquence obtained for him the honourable appellation of the *second Xenophon.*

ARRIEGE, a department of France, in the vicinity of the Pyrenees, including more than a million of square acres, and a population exceeding 191,000, and Foix is the chief town. In some places abundance of grain, wine, and excellent fruits are raised, but the larger portion of the surface is mountainous. Iron ore is abundant, and furnishes materials to a number of forges. Some other metallic ores have been found; quarries of marble are in a state of activity, and the department is well supplied with mineral springs. The river Arriege, which has its origin in the Pyrenees, traverses the department, and mingles its waters with the Garonne, not far from Toulouse.

ARSACIDÆ, a race of kings of Parthia, which commenced with Arsaces, who was the founder of the monarchy, and from whom the appellative denomination is derived. Artabanus, the last of the race, was conquered by the Persians in the 299th year of the Christian era.

ARSENIC, a metallic substance, which, in some of its combinations, is well known for its poisonous qualities. When a substance is suspected to be arsenic, or to contain any portion of that metal, a little of it thrown upon a hot iron is an easy method of detecting the arsenic. If it rise in white fumes, with the smell of garlic, the suspicion is strongly confirmed.—See CHEMISTRY and MINERALOGY.

ARSON, an English law term for wilful fire-raising; a crime which, from its nature, and the dreadful consequences which may attend it, subjects its perpetrators to the highest punishment.—See Blackstone's *Commentaries.*

ART has been defined a proper disposal of the things of nature, by human thought and experience, to be accommodated to the purposes of mankind. But art is chiefly used to denote a system of rules according to which certain actions are performed, as the art of brewing, baking, and carpentry: and in this sense art is opposed to science, which investigates the principles of art, and constructs the system of rules by which it is practised.

Arts are usually arranged under two heads, *useful* or *mechanical* arts, and *liberal, polite,* or *fine* arts. The first, which are also distinguished by the name of *trades,* require little more in their practice than manual dexterity; and hence they are called mechanical, and useful, because they are limited to the wants and uses of mankind. The liberal or the fine arts depend on mental exertion for their successful cultivation; such are, poetry, painting, music, sculpture, and architecture. Some writers even restrict the term *fine arts* to painting and sculpture; and hence it is obvious, that as the definition is framed on a wider or narrower scale, it may exclude some, or embrace all that are usually enumerated under this denomination. Utility is the object of the mechanical arts; but the object of the liberal arts is to excite agreeable sensations.

ARTA, a town of Albania, supposed by some to be the ancient Ambracia, stands in a fertile plain, which produces abundance of Indian corn, wheat, rice, and tobacco, and is at no great distance from a gulf of the same name. The approach to Arta is described as remarkably beautiful. The woods and plantations of fruit-trees in its immediate vicinity, and the mountainous amphitheatre which closes the view, form a striking and picturesque scene. Arta is the chief emporium of the southern districts of Albania; the population is estimated at 6000; and the distribution of the extraordinary number of places of worship into twenty-four Greek churches and six mosques, may serve to indicate the proportion of the Christian and

Mahometan inhabitants. The nature of the trade, which is chiefly in the hands of Greeks and Jews, has been already noticed in the account of Albania.

ARTEDI, Peter, an eminent naturalist, was born in 1705, in the province of Angermanland in Sweden; and being destined for the church, he fixed his residence at the university of Upsal, in 1724. But the strong bias to the study of natural history which had seized his mind, superseded every other pursuit; and when Linnæus was admitted a student in the same university in 1728, kindred studies soon united the two naturalists in the warmest and closest friendship. While other departments of science and natural history were not neglected, especially chemistry and botany, Artedi devoted a large share of his attention to the classification of fishes; and, for the purpose of prosecuting his favourite investigation, he visited England in 1734. The state of his finances had been always extremely circumscribed; but on his return to the continent the succeeding year, when he fortunately met with his friend Linnæus at Leyden, he was altogether destitute of the means of subsistence. The avocations of Linnæus prevented him from contributing his aid to the splendid compilation of natural history, which was undertaken and published by Seba, a learned apothecary of Amsterdam. Artedi was recommended, zealously commenced his labours in the department of fishes, and had nearly brought them to a close, when, returning from Seba's house to his lodgings, in a dark night, he fell into a canal, and was unfortunately drowned, in September 1735.

Before their separation at Upsal, Linnæus and Artedi had entered into a mutual agreement to bequeath the unpublished literary productions of each other to the survivor. Linnæus hastened to Amsterdam to claim the manuscripts of his departed friend, recovered them through the liberality of Mr Clifford, a rich citizen, who generously discharged a debt for which they were retained, and published at Leyden, in 1738, the *Bibliotheca Ichthyologica* and *Philosophia Ichthyologica*, with a biographical sketch of the author.

ARTEDIA, a genus of plants belonging to the Pentandria class.

ARTEMIDORUS, an author of some celebrity on account of his zeal and industry in collecting materials for his work on dreams. He was a native of Ephesus, and lived in the time of Antoninus Pius. To procure information on his favourite pursuit, no expense was spared in purchasing all the books on the subject within his reach, and no labour was avoided in travelling to foreign countries, or in keeping up a correspondence with individuals in distant regions. The *Oneirocritica* was published in Greek, in 1518; and Artemidorus is the author of a treatise on *Augury* and *Chiromancy*, or *Palmistry*, subjects of a kindred nature.

ARTEMISIA, a queen of Caria, and wife of Mausolus, whom she survived, and to whose memory she erected a most magnificent tomb, which was celebrated as one of the wonders of the world, and was called *Mausoleum*, from the name of the king; and hence the same name is applied in the present day to splendid monuments of the same nature.

ARTEMISIA, a genus of plants belonging to the Syngenesia class, and including the well known *Southern-wood*, *Wormwood*, and other bitter and aromatic plants.

ARTERY, is applied to the blood-vessels which convey the blood from the heart to the extremities of the body. By the veins the blood is reconducted from the extremities to the heart.

ARTICLE, a term of various signification, as denoting a clause or condition of a treaty or contract, the subdivision of a discourse or writing, a point of doctrine in religion, and a particle prefixed to nouns in different languages; as in the English language, *the* and *a*, the first of which is the definite article, as *the* man, and the second is called the indefinite, as *a* man.

ARTIFICER, a person who is employed in mechanical operations, or who manufactures any kind of commodity by means of manual dexterity, as iron, wood, flax and wool, and hence is denominated a smith, carpenter, or weaver. Artificers have been always regarded as an important class of citizens in the improved periods of society, and strict laws and regulations have been enacted for their conduct. Without referring to the rank and consideration in which artificers were held among the ancient Romans, it may be worth while to notice the laws of our own country relative to that class of society. By the law of England artificers going out of the kingdom, into any foreign country, without licence, are subjected to three months imprisonment, and a fine of L.100; and such as go abroad, and do not return within six months, after warning from the British ambassador, are treated as aliens. Those who seduce artificers to settle abroad incur a fine of L.100 and three months imprisonment; and if guilty of a second offence they are liable to a year's imprisonment, and a discretionary fine. Those who contract with artificers to settle in foreign countries are subjected to a fine of L.500, and a year's imprisonment, for each artificer contracted with. For the second offence the penalty is L.1000, and two years imprisonment. Masters of ships who give facility and effect to such contracts, are also subject to heavy penalties.

ARTILLERY, a term which, in its original signification, was applied to archery, in a general sense denotes the offensive apparatus of war, especially of a missile kind; but, in a more restricted sense, it comprehends the heavy equipage of war, as cannon, mortars, howitzers, balls, shells, &c. which otherwise come under the denomination of *ordnance*. The term *artillery*, or royal artillery, is also applied to the persons who are employed in that service, as well as to the art or science itself.

ARTILLERY PARK is that place, in a camp, which is appropriated to the artillery.

ARTILLERY TRAIN, a number of pieces of ordnance mounted on carriages, with all their equipage, ready for service.

ARTILLERY COMPANY, an association of the citizens of London, which was first instituted in 1585. In a short time this body increased to three hundred; and in 1588, when the whole kingdom was thrown into the utmost consternation and alarm by the invasion of the Spanish armada, some of the members held commissions from the queen. In 1611 the company was revived and amounted to 6000. The artillery company is now a corps of infantry, composed of gentlemen of property, to which a division of archers is attached.

ARTIST, in its general signification, is applied to a person who is skilled in the knowledge or practice of some art; but, in a more restricted sense, is limited to a proficient in some of the fine arts, as painting, engraving, sculpture, or architecture, and in this sense it is opposed to artificer or artizan, signifying a person who is occupied in a mechanical art.

ARTOCARPUS, THE BREAD FRUIT TREE, a genus of plants belonging to the Monoecia class, and including two species of that remarkable vegetable production. See BOTANY.

ARTOIS, a late province of France, and one of the most fertile in the kingdom, is now included in the department of the Straits of Calais, has a considerable trade in grain, flax, woollen and linen cloth, and some of the chief towns are, Arras the capital, Bethune, St Venant, and St Omer.

ARVALES FRATRES were a college of twelve priests, among the Romans, which was instituted by Romulus, and selected from the families of the first rank in the state. They officiated in the sacrifices of the *Ambarvalia*, which were annually offered to Ceres and Bacchus, for an abundant harvest.

ARUM, WAKE-ROBIN, or CUCKOWPINT, a genus of plants belonging to the class Gynandria, one species of which, *maculatum*, is a native of Britain.

ARUNDEL, a market-town of Sussex, in England, which stands on the declivity of a hill, on the banks of the river Arun. The river is navigable for small vessels; the population is about 2000; coarse cloth, for hop bags, is manufactured, and timber in considerable quantities is shipped for the dock-yards. The ancient castellated mansion, belonging to the Duke of Norfolk, which has been lately repaired, is a fine ornament to the town. Arundel is 55 miles south-west from London.

ARUNDELIAN MARBLES, are ancient monuments which were collected in Greece, or in the islands of the Archipelago, at the expence of Thomas Howard, Earl of Arundel, and from him the name is derived. They were presented to the university of Oxford by his grandson, and hence they are called the *Oxford marbles*; and the inscriptions, according to some opinions, having been executed in the island of Paros, they have received the name of the *Parian Chronicle*. During the residence of the Earl of Arundel in Italy, he employed Mr William Petty, a learned antiquary and profound classical scholar, to travel in Greece, and the contiguous islands, for the purpose of purchasing and collecting whatever remains of antiquity should fall within his reach. The fruits of this expensive, and often hazardous enterprise, was the splendid collection, composed of 37 statues, 128 busts, and 250 tablets of marble, with inscriptions, besides gems and other fragments, and the whole reached England in 1627. The marbles containing the inscriptions were inserted in the garden-wall of Arundel-house, in London, and immediately attracted the notice of antiquaries, and especially of the learned Selden, who transcribed a number of the inscriptions, and published them under the title of *Marmora Arundeliana*. But these curious fragments suffered great depredations during the civil wars; and when they were presented in 1667 to the university of Oxford, the number of stones was reduced to 130. The learning, industry, and ingenuity of the antiquary, were again occupied in decyphering and explaining the inscriptions. Dean Prideaux published *Marmora Oxoniensia* in 1676; the work of Maittaire on the same subject appeared in 1731; and Dr Chandler brought forward a new edition in 1763. Doubts of the authenticity of the inscriptions had been occasionally thrown out by different authors, although a contrary opinion was most generally adopted; but the claims for the high antiquity of these monuments has been more formally challenged by Mr Robertson in his work entitled the *Parian Chronicle*, than by any former author, and the objections urged against their alleged authority are stated with much learning and ingenuity. But for a full detail of his arguments, the reader, interested in such curious researches, is referred to the Essay itself, as well as to *The Vindication of the Parian Chronicle*, by Hewlet; and to Dallaway's *Anecdotes of the Arts*.

ARUNDO, the Reed, a genus of plants belonging to the Triandria class.

ARUSPICES, or HARUSPICES, an order of priests among the Romans, who presided at sacrifices for the purpose of inspecting the entrails of the victims which were offered, and from their aspect, as well as from other incidents which attended the sacrifice, of announcing whether the omens were favourable or adverse. The observations of the aruspices were derived from the appearance of the victims before they were killed, and of the entrails after they were cut up, from the flame which arose from the altar during the burning, and from the flour, frankincense, and wine, used in the sacrifice. The same priests were consulted concerning portents and prodigies, to declare what were the omens to be learned from such preternatural appearances. This order was selected from the best families in Rome.

ARZILLA, a sea-port town in Morocco, which stands at the mouth of a small river which flows into the Atlantic ocean, was originally a Roman colony, was afterwards taken by the Goths, and finally came under the dominion of the Mahometans, who adorned it with many splendid edifices. The inhabitants, who are chiefly Moors and Jews, amount to about a thousand.

AS, a Roman weight and coin. The weight was equal to 12 ounces, or the Roman pound. The coin of the same name varied in weight and value at different periods of the commonwealth, and it was composed of different materials, as wood, leather, shells, and brass. The weight, originally 12 ounces, was reduced at different times, till at last it was diminished to half-an-ounce.

ASA-*Fœtida* is the concrete juice, or extract, of an umbelliferous plant, which is a native of different regions of Asia. See *Ferula*, under MATERIA MEDICA.

ASAM, a country of Asia. See ASSAM.

ASAPH, ST. a small town of Flintshire, in England, with a population little exceeding 1500, and chiefly known as being the see of a bishop. The situation of St Asaph is in a fertile valley, at the confluence of two rivers, and it is 20 miles distant from Chester.

ASARUM, Asarabacca, a genus of plants belonging to the Dodecandria class.

ASBESTUS, or Asbestos, a mineral substance belonging to the Magnesian genus, and of which the ancients manufactured their celebrated incombustible cloth. See Mineralogy.

ASCARIS, a genus of worms belonging to the order Intestina. See Helminthology.

ASCENSION, an astronomical term, which is said to be either right or oblique. *Right Ascension* is an arch of the equator, intercepted between the equinoxial point, or the first of Aries, and the hour circle of any planet or star. *Oblique ascension* is that point of the equinoxial which comes to the horizon with any of the planets or fixed stars.

ASCENSION ISLAND, an island in the Atlantic ocean, discovered by the Portuguese in the beginning of the 16th century, is about 10 miles in length, and 6 or 7 miles in breadth. The shores in many places are covered with a fine sand of dazzling whiteness, and the surface of the interior regions presents a mass of rugged rocks, piled on each other in great disorder, with a few spots on which some scanty herbage finds nourishment, but no tree or shrub has yet reared its head to conceal its parched and barren aspect. Limestone seems to be the prevailing rock. A peculiar species of grass, *Aristida Ascensionis*, is the most common of the vegetable productions, five different species of which were all that Osbeck, who visited the island before the middle of the 18th century, could discover. Turtles of large size, and fish, are abundant round the shores; land crabs are common; it is the frequent resort of numerous sea-fowl; and goats, the breed of which had been left by early voyagers, have greatly multiplied. A volcanic origin is ascribed to this island by those who describe its appearance. S. Lat. 8° and W. Long. 14°.

ASCETIC, from the Greek, signifying *to exercise*, an appellation applied to a person who subjects himself, from religious motives, to severe mortification and penance.

ASCHAM, Roger, a learned Englishman, who was greatly distinguished by his classical literature, was a native of Yorkshire, and was born in 1515. His parents were remarkable for having terminated the long period of 67 years of a happy married life on the same day and nearly in the same hour. Of them it might be justly said, they "were pleasant in their lives, and in their death they were not divided." Adopted into the family of Sir Anthony Wingfield, and placed under the care of the tutor of his sons, young Ascham made rapid progress in classical literature. In 1530, by the generosity of his patron, he was admitted a student in Cambridge; and the new studies of literature, and new tenets of religion, which had just begun to dawn on the world, gave full employment to all who were desirous of truth or ambitious of fame, and failed not to awaken the energies of his youthful mind. The Greek language was the first object of his study; and such was his zeal and ardour to become a proficient in its knowledge, that, even in his boyish years, he read lectures to others who desired instruction. To this mode of improvement he was recommended by the advice of a friend, a warm admirer of Grecian literature, who, in a letter which is worthy of being recorded, assured him that he would gain more knowledge by explaining a fable of Æsop to a boy, than by hearing one of Homer's poems explained by another.

Soon after he was admitted to a bachelor's degree; in 1534, when he was in his 18th year, he was elected fellow of his college. His reputation as a Greek scholar rose high, and his chamber was often frequented by those who were eager to hear his lectures on Grecian literature. Three years afterwards he became master of arts, and commenced tutor, and soon after was appointed public lecturer on the Greek language, the first establishment of the kind in the university of Cambridge. Ascham had before this time learned to perform on musical instruments, and he excelled in the art of writing, particularly in the embellishment and illumination of the pages, mechanical accomplishments which were then greatly admired, and added much to his celebrity. These qualifications, and the elegance of his Latin composition, rendered him a fit person to write the public letters of the university. His feeble constitution, which was not invigorated by close study, required him to take exercise in the open air. Archery was his favourite amusement; and in a work on the subject, entitled *Toxophilus*, he delivers precepts for teaching the art, and strongly recommends the practice.

The talents and reputation of Ascham obtained for him the notice of Henry VIII., with a more solid mark of royal approbation in a pension of L. 10 a-year, a sum which now appears nominally small, but is supposed to be equal to L.100 in the present time. He succeeded to the office of orator of the university, and was at the same time employed in teaching the sons and daughters of the nobility the learned languages, and also in writing a fine hand. The princess Elizabeth and Prince Edward were among the number of his pupils. He was engaged for some time in directing the studies of the princess; but on some disgust which is not explained, he suddenly relinquished the employment, and returned to his retirement in the university. He visited Germany in the capacity of secretary to the English ambassador, and drew up a *A Report and Discourse of the Affairs* of that country. The death of Edward disappointed all his hopes. Recalled from his diplomatic situation, he returned to his fellowship in despair; but he recovered sufficient influence to be reinstated in the office of Latin secretary under Philip and Mary, with an annual salary of L.20; and a specimen of his laborious industry is recorded, in composing and transscribing, with great elegance, 47 letters in three days, addressed to princes and personages of the highest rank in Europe. It is not a little singular, that a protestant held so conspicuous a situation under that intolerant reign. When Elizabeth mounted the throne in 1558 he was continued in his office, and admitted to assist her in her studies, and even to share in her diversions; but this seeming favour added little to the improvement of his fortune. His only literary production during her reign was the *Schoolmaster*, or, a Treatise on Education, great part of which was composed under the pressure of pecuniary distress, occasioned either by the parsimony of the queen, or his own improvident expenditure. The bodily constitution of Ascham was never robust, but in the latter period of his life it was greatly enfeebled by intense study; and in his assiduous application in the composition of a poem which was to be presented to the queen on the anniversary of her accession, he was seized with an illness which brought him to the grave in 1568, leaving behind him the character of one of the most learned men and most accomplished scholars of the age. See *the Life of Ascham* by Dr Johnson.

ASCIDIA, a genus of Vermes belonging to the order *Mollusca*. See HELMINTHOLOGY.

ASCLEPIAS, SWALLOW-WORT, a genus of plants belonging to the Pentandria class.

ASCYRUM, PETER'S WORT, a genus of plants belonging to the Polyadelphia class.

ASHBURTON, a borough town of Devonshire, and one of the Stannary towns, in the vicinity of which the copper and tin mines are successfully wrought. The population exceeds 3000, some of whom are occupied in the manufacture of serges. The distance from Exeter is 19 miles.

ASHBY DE LA ZOUCH, a town of Leicestershire, with a population of nearly 3000, and having a considerable trade in malt, and 19 miles distant from Leicester.

ASHMOLE, ELIAS, a learned and industrious English antiquary, was born at Lichfield in the year 1617, and, after completing his education in the country, entered into the profession of an attorney in London. But when the civil war broke out he joined the army, and served in the ordnance department; and during his residence at Oxford in a military capacity, he enrolled himself as a member of one of the colleges, and prosecuted the study of mathematics, natural philosophy, and astrology. After the surrender of Worcester, Mr Ashmole went to London, where kindred pursuits introduced him to Lilly, Moore, and Booker, the celebrated astrologers of the age. A second marriage had greatly improved his fortune, and his house became the frequent resort of all those who were engaged in alchemical and astrological researches. He published a Treatise on Alchemy under a fictitious name, and made a collection of the manuscript works of English chemists, which appeared in 1652, with the title of *Theatrum Chymicum Britannicum*.

The studies of Ashmole took a different turn. Antiquarian researches seem to have occupied his attention during the remainder of his life. His work on *The Institution, Laws, &c. of the Order of the Garter*, published in 1672, acquired great celebrity. The loyalty of Ashmole was rewarded at the restoration of Charles, by his appointment to the office of Windsor herald and superintendant of the king's medals, besides some other lucrative situations and literary honours. He had made an extensive collection of coins; but his cabinet, which contained nine thousand coins, with his library and antiquities, was destroyed by fire in his apartments in the Middle Temple. His gold medals, and some valuable manuscripts, were fortunately preserved. Mr Ashmole had resided in the house of John Tradescant, the celebrated botanist, at Lambeth, and his collection of curiosities, which were bequeathed to him, along with his own books and manuscripts, formed the foundation of the Ashmolean Museum at Oxford, which is deposited in a building designed by Sir Christopher Wren. Mr Ashmole died in 1692.

ASIA.

ASIA is one of the larger portions of our globe, which, by its magnitude, the vast modifications of its features, the variety of its productions, the extent and antiquity of its population, merits very ample description; but as the constituent parts are to be particularly treated in the order of the alphabet, we shall at present confine our attention to some general topics in its natural history, and the progress of its discovery and civilization.

Extent, &c.—Asia is connected with Europe by the great chain of the Uralian mountains, and with Africa by the narrow isthmus of Suez. It lies, therefore, to the east of these continents, stretching out in a very irregular manner towards the Great Pacific Ocean, by which it is separated from the later known continent of America; while its southern shores are washed by the Indian Ocean, taken in its largest acceptation; and its limits on the north are defined by the ever-during ice of the arctic regions. The greatest length, supposed to be from the strait of Babelmandel, in Arabia, to a point at Behring's strait, in the north-east, exceeds 8000 British miles; and its breadth, reckoning from the southern cape of the peninsula of Malacca, to a cape in the north-west of Siberia, may be said to be 5000. The medial dimensions are, perhaps, 1000 miles less. This is altogether exclusive of a multiplicity of islands scattered around its coasts, particularly in the south and east, some of which are of magnitude sufficient to form considerable kingdoms.

The extreme irregularity of Asia will be best understood by inspecting a map. In artificial or scientific geography, it is said to be situate between the 26° and 190° of longitude east from Greenwich, and between the 2° and 77° of north latitude. Its most imperfect boundary is in the direction of Europe, being in a great degree arbitrary, and consequently variously assigned by different authors. It is enough for our purpose to conceive an imaginary line drawn from the Uralian mountains, already mentioned, to the small river Karposka, which rises near Sarepta, and runs into the Don, and to follow the course of this last river into the Black Sea, whence, through the Dardanelles to the Mediterranean archipelago, a natural and sufficient boundary is presented.

General appearance.—To a spectator, whose eye could take in the whole of this continent at one view, Asia would seem to consist of a vast elevated plain, bounded by mountainous ridges, whose declivities, proceeding in all directions, and in various lengths, formed the basis of many empires or states, only narrowly divided from each other by series of hills and rivers. This central elevation, which is some thousand miles in extent, is perhaps its most striking feature, distinguishing Asia from all the other continents, besides giving rise to a peculiar distribution of rivers, and at the same time materially influencing both its own temperature and seasons, and those also of another large portion of the globe, Europe. The plain itself is but scantily inhabited, and little known; few travellers having surmounted the natural difficulties with which it is environed, or choosing to trust themselves in the hands of the barbarians by whom it is possessed. On the north of the plain extends the bleak Siberia, doomed to almost perpetual winter, not so much from its geographical position as the height of its boundary, which interrupts the current of warm air from the more favoured countries of the south. These, again, which are the vast states generally classed under the title of India, and a large portion of the Chinese empire, are prevented, by the same arrangement, from experiencing the diffused severity of the polar clime. Towards the east of the plain, we find those parts of China and Chinese-Tartary which border on the Pacific ocean; and on the west are Persia and the countries extending from the vicinity of the Aral and Caspian seas towards the frontiers of Europe. Such is the most general distribution of the Asiatic lands; and several extensive tracts, not exactly included in any arrangement, may be considered as appendages. The chief of these are, that large space included between the Mediterranean, Red sea, part of the Indian ocean, the Persian gulf, and a line stretching from it towards the Black sea, and which comprehends Arabia, Syria, and Asia Minor, along with some smaller divisions, altogether forming the south-west border of Asia; the promontories of Kamtschatka, Sachalin, (conceived, according to Krusenstern, as not disunited from the continent by the the gulf of Tartary,) and Corea, on the east, and the still more important projection in the south, constituting the countries of Cochin-China, Cambodia, and Siam, with Malacca, projecting, as it were, between two seas. To all of which must be added, as at comparatively small distances, the extensive and sometimes grouped islands of Japan, Formosa, Hainan, Sumatra, Ceylon, &c. not to speak of many more which are farther off, and which, by an arrangement pretty generally adopted among modern geographers, enter into the formation of another large division of the globe recognised under the appropriate enough title of Australasia.

Mountains.—The mountains of Asia are numerous, distributed in vast clusters and long ranges, generally fixed on plains greatly elevated above the sea, in certain countries constantly covered with snow even in southern latitudes, and of course giving rise to many rivers, some of which are only inferior to one or two of the mighty waters to be found in the new continent. In respect of height, it was always imagined till lately, that none of the mountains in Asia equalled those of South America. A different opinion is now entertained; and it is supposed that this continent presents the greatest elevations on our globe. According to Colonel Crawford's observations, a peak of the Himala, or Snowy mountains, to the north of the British dominions in India, seen from Patna, is 20,000 feet higher than Nepaul, which is conceived to be 5000 feet above the sea; and still more recently, Mr Moorcroft has actually crossed these mountains, " whose height *has been found* to extend from 21,000 to 24,000 feet above the level of the plain out of which they spring."—*Quart. Review*, 1815.

The Altaian chain, one of the most considerable on the globe, running a course of nearly 5000 miles, may be considered as the northern face, or ridge, of the central region. The Uralian chain appears, at least in some maps, to arise from the westernmost branches of the Altaian, and to proceed thence almost due north towards the polar region, forming, as already mentioned, part of the western boundary of Asia. The Taurian chain, or mountains of Taurus, may be considered the counter-part of the Uralian, issuing from the western point of the central plain, and traversing the kingdom of Persia towards the south; but part of this chain, as we conceive it to be, under the well-known name of Caucasus, or Caucassian, in the largest sense, takes a northerly route, filling up much of the space between the Caspian and Black seas, and also sending off branches, under various names, towards the shores of the Mediterranean. The mountains of Thibet, which are entitled to be held as part of the southern front of the central range, appear to take a kind of circular direction, the concavity of which is turned towards the south. Smaller ridges are found traversing most of the Asiatic countries, especially in the vicinity of the sea-coast. The more striking detached hills or mountains of this continent are, Sinai and Horeb, in Arabia; the well-known mounts or hills of Palestine and Syria, alluded to in sacred scripture; Olympus, Rhea, and Ida, in Asia Minor; and Ararat, to the east of Armenia, but belonging to Persia.

Seas and Lakes.—Asia presents some remarkable collections of water detached from other seas, to which the name of lakes might be given, if their magnitude did not seem to require a more noble title. The chief of these is the Caspian sea, lying between Independent Tartary on the east, Persia on the south, the Turkish dominions on the west, and those of Russia on the north. It is about 700 miles long, from north to south, and between 100 and 200 miles broad from east to west, and is the receptacle of many important rivers. To the east, at the distance of about 100 miles, is another, but much smaller lake, denominated the sea of Aral, which by many writers, on tolerably good evidence, is imagined to have once been united with the Caspian. It is 200 miles long, nearly in the same direction, and about 70 broad, and also receives several rivers. Both of these seas consist of salt water, a circumstance in which they differ from the lakes or seas of Canada in North America. The lake of Baikal, near the middle of the southern part of Siberia, is a collection of fresh water, upwards of 300 miles in length, and not exceeding 35 in breadth. The central plain of Asia is supposed to contain several large lakes, but of these we have little information. Of those which are found elsewhere, and which are inferior to any now mentioned, it will be necessary to take notice in the accounts of individual countries.

Rivers.—The rivers of Asia are numerous, and often of great magnitude, corresponding with the height and extent of the mountains where they take their rise. The chief are the Kian-Ku and the Hoan-Ho, both rivers of China, and probably the largest in the world; the Ob, or Oby, the Yenisei, and the Lena, besides other very considerable rivers, all belonging to Asiatic Russia; the Amur, properly speaking a river of Chinese Tartary; the Ganges, Burrampooter, and Indus, of India; the Euphrates and Tigris. The origin of most of these and many other rivers, as might be expected, is to be found in the elevated lands which traverse the interior of this continent, from which they descend in all directions, as may readily be understood from the previous description of the central regions. On the whole, this continent is plentifully supplied with water, an advantage accruing from its peculiar conformation, and productive of some of the most essential benefits of which it can boast.

Climate, &c.—The climate and soil of Asia are extremely diversified. As but a small part of it is within the tropics, the heat is never so great as in some of the central countries of Africa. It would be difficult to find a single natural production in any other quarter of the globe, which cannot be paralleled in some part of Asia; and, on the other hand, it is to Asia, in a particular manner, that all the rest of the world looks for some of the chief luxuries and most desireable excitements of animal life. This remark may suffice instead of any enumeration of the various delightful objects in which it is so prolific.

Nor is it necessary to occupy any room in the zoology of Asia, which in fact is an epitome of the whole globe. A few different species are found indeed in America, and some varieties may be met with in the other two continents; but these exceptions are totally insignificant on the great scale to which we are now confining our attention. The same remark is equally applicable to the mineralogy of Asia.

Population, &c.—Asia is undoubtedly the birth place of mankind, and appears to have been specially adapted for that purpose. A more suitable spot could not be selected for the support and propagation of our species in an early stage of their existence, than is to be met with in some of its southern regions; and its extensive plains were no less proper for preserving many families together, till they had made such advancement in the knowledge of the necessary arts as would permit their separation with safety. But the ease with which nature produces her fruits, and the great abundance to be found in these regions, were not so well fitted for calling forth exertion and ingenuity on the part of man when he had attained a state of maturity. Some degree of difficulty is essential to his highest improvement. The chief excellencies of human intellect, indeed, are not the offspring of indulgence, though a plentiful supply of the necessaries of life be required for their developement. Here again, we may discover an appropriate adaptation of this continent to the state of our species beyond the period of infancy. It is connected with Europe and Africa in such a manner as to allow a ready transition, before mankind could be either able by their art, or prompted by their necessities, to trust themselves on any other element than the earth; and it is impossible to doubt that this circumstance, in its structure and relations, was really intended for the effect which we have every evidence for the belief was produced by it, the gradual extension of mankind over the rest of the earth. This is well illustrated by Dr Millar, in his "Philosophy of Modern History," to which we refer.

Linnæus, and other writers, have given tables of the varieties of the population exhibited in Asia. They are necessarily imperfect, as our acquaintance with many parts of this continent is still incomplete; but they have their use in the prosecution of history, as directing attention to the origin and relations of different nations. The amount of population has probably been over-rated at 500,000,000. But after making every reasonable allowance for exaggeration, particularly in the case of China, the number must be allowed to be a striking proof of the fertility and advantages of this continent. Without pretending to much accuracy, which is impracticable in this case, but in order to afford some general notions on the subject, we are induced to suppose the population of Asia and Australasia equal to a thousand parts, of the greater part of which our calculation furnishes us with the following proportional table.

Names of Countries.	No. of Parts
China	580
Hindoostan, in the largest sense, including from Cabul to Assam, and the island of Ceylon	170
Japan	60
Birman empire, including Siam, &c.	58
Persia	30
Asiatic Turkey, including Syria, &c.	26
Chinese Tartary, with Corea	18
Asiatic Russia	16
Arabia	14
Australasia	8
Cochin China, Tunquin, Laos, &c.	8
Independent Tartary	6
Malacca, with Sumatra	4
Thibet	2
	1000

Though drawn up with great pains, after a due consideration of many circumstances, this table cannot claim any other respect than as a mere attempt at approximation to the truth. The chief difficulty which it exhibits is the amazing proportion allotted to China, a country in reality of much less extent than what we have classified here as Hindoostan. Yet it is impossible, we believe, without very unwarrantable and very invidious surmises, to reduce the estimate. Admitting its correctness, then, we must either think less favourably than some of their advocates, of the manners, of the government, and the natural advantages of the Hindoos, or we must believe that the Chinese have discovered certain principles of policy still unknown to the greater part of mankind. The case of Japan, indeed, is very similar, nay, if any thing, more remarkable, as may easily be seen

Asia. by comparing the accounts of its extent with its alleged population. But the fact is, that of both these countries our information is so doubtful, and so contradictory, as to give rise to strange and discordant opinions.

Governments and State of Society, &c.—With some few exceptions, the whole of Asia may be said to be subjected to the despotic rule of a few individuals. Of a liberal government, not to speak of a republic, there is perhaps not an example to be found in the immense space between the Red sea and the Pacific ocean. So true it is, that by much the greater portion of mankind has never been redeemed from a state of slavery; for surely those must be called slaves who have neither rights nor property independent of the will of others, and whose lives and happiness are continually exposed to the fatal attacks of caprice and envy. Constitutional checks on power are utterly unknown in practice, and the semblance of them, in a few countries, must rather furnish an additional source of regret to those who have the smallest conception of their value. The only tried modes of avoiding the evils of tyranny are flattery and rebellion,—but flattery implies one of the worst evils, complete degradation of mind; and rebellion, again, only shifts the burden, or changes the sufferers, besides immediately producing some great miseries, which render the transition altogether a very doubtful relief. The established religions, in general, are no less unfriendly to the best interests of mankind, and serve still more effectually to perpetuate the weakness and barbarism of intellect which prevail. Superstitions of the most disgusting kind, and ceremonies from which common feeling, and common sense, recoil, supply the place of national doctrines and decent manners. But, in one respect, they are not unsuitable to the constitutions of the people, as they neither prompt to the exercise of the understanding, nor impose severe restraints on the inclination for sensual delights. Asia, therefore, presents few instances of highly cultivated faculties, and fewer of virtuous self-denial. But we should err if we imagined that intellect is altogether dormant, or that debauchery has grown to rankness in eastern countries. Some portion of mind is still required for the study and practice of the arts and sciences, limited as they are in kind, and scarcely advanced by one effort above the degree in which they existed several centuries ago, while the very nature of the climate retards the progress of licentiousness by enfeebling its powers. Rudeness and civility, pride and obsequiousness, simplicity and craft, are variously blended in the character of the people, forming a mass calculated to excite pity and contempt, rather than hatred or indignation, in the mind of an European. A charm is sometimes lent to it, by a vividness, or, more correctly speaking, a gaudiness of imagination, which displays itself in pompous expressions, and frequent allusions to the beauties of early poetry. Strangers are taken with this illusion; but it is soon properly referred to an early and irresistible acquaintance with the ornamental parts of nature, and has little or no connexion with the creative efforts of genius. Their works of taste partake of the same principle and rarely deserve any other praise than what is bestowed on happy imitations. The commercial transactions of the various countries are quite inconsiderable, and far from being conducted on the systematic principles, or prosecuted with the ardour of Europe. Very little of the sea-coast, which seems so favourable for it, is yet recognized in the annals of trade, and those parts which are most noted for advancement in this respect, have been indebted to the labours and zeal of persons who have gone in search of wealth from the western world. Altogether, the condition of mankind in Asia is more to be deplored than envied; and the disposition, the habits, and prejudices of the people being considered, together with the puny results of any experiments which have hitherto been made for its amelioration, there remains but small hope to the philanthropist, that it will be speedily or generally improved.

Progress of Discovery.—To the time of Ptolemy, or about the second century of the Christian era, the ancients appear not to have known more than a quarter of this continent. The reasons are easily explained;—many parts of it were uninhabited,—those which were most cultivated were far removed from the theatre of European concerns,—the science of discovery was in its infancy, or rather indeed had not commenced,—the spirit of commerce had not received aid from political motives,—navigation was confined to mere coasting voyages,—and travelling was dangerous, if not impracticable, beyond the limits of well organised society. The chief discoveries of the ancients were effected through the medium of war, and were rather incidental than the result of studied design and previous contemplation.

By the Egyptians.—Sesostris, one of the monarchs of Egypt, is said, at a very early period, to have led an army through a large portion of Asia, in which he established colonies. But the accounts of his life and operations are far from being entitled to implicit credit; nor do his alleged transactions in the east receive confirmation from the records of any of those countries which he is reported to have visited. The Egyptians, in general, were averse both to commerce and to intimacy with strangers. It may be well doubted, therefore, if the conquests of Sesostris, even admitting their truth, produced any important or permanent advantage.

By the Phœnicians.—The Phœnicians, a colony from Egypt, did not inherit the prejudices of their ancestors. They engaged extensively in commerce, which they carried on not only with various parts of Africa, and some of the coast countries of Europe, at this time scarcely emerged from the chaos of nature, but also with various places in the east. To this people, then, we may ascribe much of the information respecting Asia which existed in the ancient world, though the particulars of their progress are lost in the wreck of all their historical records.

By the Greeks.—The Greeks had commonly too much employment at home, during the most interesting periods of their history, to concern themselves greatly with the affairs of distant regions. Their philosophers, indeed, travelled abroad for the sake of improvement, but the result of their labours was favourable to almost any other science more than to geography. Herodotus the historian, who lived nearly five centuries before the Christian era, is with propriety considered as master of all the knowledge of it that existed in his day. He is, comparatively, copious on the subject of Asia; and, as far as can be ascertained, there does not appear to have been a great deal added to his observations, nor much corrections of his errors, up to the time of the Macedonian conqueror.

Under Alexander and his successors.—To the skilful and energetic undertakings of Alexander, must be ascribed a larger share of geographical discoveries in this continent than had been effected by all the philosophers and travellers that preceded him. Persia was laid open by his victories; the river Indus bore his fleet into the ocean, by which again it was carried through the Persian gulf to the Euphrates; India experienced alike the invincibility of his arms and the beneficence of his policy. His death, which occurred either too early or too late for his fame, did not altogether extinguish the light of discovery, though none of his successors had the talents or the judgment, or at least the good fortune, to profit much by his example. Seleucus, indeed, penetrated much beyond his progress, and sent one of his officers to Palibothra, on the Ganges, now probably for the first time seen by any European. But his advance farther to the east was prevented by the necessity of returning to defend his dominions, which had been threatened with invasion by Antigonus; and the subsequent prosecution of commerce, principally under the patronage of the Ptolemies, had scarcely any other effect on the science of geography than merely preserving the information that had been previously acquired.

The Greek princes of the kingdom of Bactria, originally subject to Seleucus, but ultimately become an independent state, appear to have maintained a commercial intercourse with India, and even to have extended their conquests in that country long after the death of Alexander. They assumed at one time the title of *Great King*, which, after every allowance for the exaggerations of vanity, argues, in some degree, the magnitude of their dominions as well as the supremacy of their power. During their continuance in this state of prosperity, it is highly probable that their countrymen towards the west would have many opportunities of cultivating an acquaintance with several parts of Asia, not only by their own observations in the course of their commercial pursuits, but also through the reports of such of the natives as were induced to form friendly and occasional alliances with them. Had this kingdom been prolonged, it is not to be doubted that Europeans would have earlier and more extensively contributed to the improvement of the geography of Asia. After an establishment of about 130 years, and nearly about the same space of time before the Christian era, it was completely overwhelmed by a horde of Tartars who had been driven from their native country on the confines of China, by a still more powerful body in their rear. Thus terminated the last fragment of the Macedonian conquests, and the door was shut for ages on European ambition and enterprise in these regions.

By the Arabians.—Ptolemy's work, which probably contained all the geography of his time, affords a very imperfect and highly erroneous delineation of Asia. But his mistakes, as well as his excellencies, were respected and copied, with little or no variation, for many centuries. The Arabians, indeed, under the impulse of a new faith, pursued both conquest and discovery in Asia, and, in several respects, advanced geography much beyond the prevalent notions. But their discoveries were either unknown to Europeans, or were disregarded, from an aversion to their religion, with the success of which they were perhaps imagined to be connected. It is only in modern times, accordingly, that justice has been done to the attainments of that singular people.

By the earlier moderns.—Cosmas, an Egyptian merchant in the reign of Justinian, made several voyages to India, of which he gives an account in his work entitled *Christian topography.* Together with a great deal of fanciful matter, this production contains some additional information respecting the west coast of India, apparently the result of careful and considerate observation. We learn from it, that in his time all the large ports of India were frequented by traders from Persia; and, which is a striking proof of the intercourse between these two countries, that in most of the cities of any note in India there were Christian churches established, the priests of which were ordained by the archbishop of Seleucia, the capital of the Persian empire, to whose jurisdiction they still continued subject. Alfred, king of England, in the 9th century, appears to have heard of the existence of these churches, and to have testified his regard for the common faith, as well as the interests of science, by the mission of Sighelm, afterwards made bishop of Shireburn, with presents to the shrine of St Thomas and St Bartholomew, on the Coromandel coast.

In the middle ages.—A taste for the luxuries of the east, which had survived the glory of the Roman empire, and even gained strength, notwithstanding the disasters of the times, urged the Italians, and some other people on the shores of the Mediterranean, to open a trade with Constantinople, and also to visit occasionally the ports of Syria and Egypt. In this latter case, the aversion of the parties to each other, on a religious account, was suspended or soothed by an experience of the mutual benefits arising from commercial intercourse. Important efforts might have been the consequence throughout the world, had the same good sense continued to operate. But the spirit of the crusades, which soon afterwards arose, and which for two centuries embittered the militant controvertists, gave a decisive check to this friendly understanding. The conquests of the Christians in Syria only increased their regret at the ultimate triumph of the Mahometan arms. Some partial light was communicated to geography during these impolitic expeditions. The encouragement afforded to the maritime states of the Mediterranean, the intercommunity established amongst the various countries of Europe, all engaged in the same cause, and the protection afforded from a conviction of their necessity and value to the interests of commerce, whenever they did not interfere with the primary objects of the enterprise, were still more substantial benefits. Nor ought we to omit mentioning the conquest of Constantinople by the Venetians and the chiefs of the fourth crusade, which took place in the commencement of the 13th century, as an event materially conducive to the preservation of an intercourse with the eastern regions. The great motive which led to this step, so inconsistent with the principles of the crusaders, and which afterwards influenced the Genoese to dispossess their rivals, was the desire of engrossing the trade with India, destined never to be lost sight of in the contentions and revolutions of Europe.

On the revival of letters.—The records of the 13th century allude to some other events directly conducive to the progress of Asiatic geography; among which are chiefly to be noted the missions of Pope Innocent IV. and St Louis IX. of France to the court of the emperor of the Moguls, a new and victorious power which had arisen in the heart of Asia, and the still more interesting travels of Marco Polo as far as to the frontiers of China. This remarkable person, by birth a Venetian, after having carried on trade for some time with several of the cities in Asia Minor, ventured to penetrate still farther into the east, and at last arrived at the court of the Great Khan, by whom he was favourably received, and employed in important services for many years. On his return to Venice, he published the account of his travels, which soon astonished all Europe, by a disclosure of mighty empires, and vast regions, far beyond the supposed boundary of the world. China is mentioned by him under the name of Cathay, by which it has been long known in the east. Having travelled through some of the provinces, he speaks particularly of several of its cities. Different parts of Hindostan are specified, and even sometimes by their present names, as Bengal and Guzzerat, both said to be opulent kingdoms. He visited many of the islands in the Indian ocean, besides the coast of Malabar, as far as the gulf of Cambay. This survey, the most extensive which had hitherto been made in these regions by any European, was proportionally important in its effects, though, in the peculiar circumstances of Europe, a considerable time was required for its full operation. The Venetians, in the meanwhile, enjoyed the advantages of superior commercial intercourse with the east, notwithstanding the attempts of the Genoese and other states to obtain a share.

By the Portuguese.—At no period did the prosperity of these republicans, as dependent on this trade, appear to be more firmly secured against successful rivalship than towards the end of the fifteenth century, when the discovery of a new course to India, by the Cape of Good Hope, effected by the Portuguese, occasioned its rapid and irrecoverable declension. This great event constituted an era in geography and in the history of mankind. Its immediate effect was an acquaintance with the coasts of Asia, vastly greater than had ever before been formed. The Portuguese speedily availed themselves of it to reach the countries of Cambodia and China, to possess the islands of the Indian archipelago, and to establish commercial colonies throughout a space of more than twelve thousand miles extent. The trifling discoveries made in the preceding century, by the travels of Oderico, a Venetian friar, Sir John Mandeville, an Englishman, and others, are totally unworthy of regard in the view of this splendid achievement.

By other Europeans.—For about a century, the Portuguese enjoyed the commercial sovereignty of the east, uninterrupted by the interference of any European. At last, the Dutch, having conquered their freedom from the tyranny of Spain, and making strenuous efforts for national consequence, appeared as their rivals. To them succeeded the English, with a rapidity which nothing could withstand, and with a success which still continues to enhance the dominions and the power of Britain. Since this period the geography of Asia has rapidly improved; but it is still imperfect, especially as to the central and northern regions. We cannot better indicate the amount or nature of the modern acquisitions than by specifying a few of the most valuable accounts of modern travels in its various regions. This we shall do much in the order of a French work, little known in our country, but to which one of our most popular geographers has been more extensively indebted than he has had the candour to acknowledge. It is entitled "Bibliothéque Universelle des Voyages, &c. par G. Boucher de la Richarderie." Paris, 1808, in 6 vols. 8vo. Our notices, which are select, may assist the studious reader in directing his attention to some of the best sources of information; but we are far from purposing to give a catalogue of titles more calculated to disgust the eye and exhaust the patience, than to convey instruction or save labour.

A List of Works proper to be consulted on the subject of Asia, arranged according to the geographical position of its various regions.

1. Asiatic Turkey, comprehending Syria, Palestine, some of the Mediterranean islands, &c.

Few works treat of the geography or natural history of these countries; most of them are occupied with antiquities, and researches into the opinions and customs of certain religious sects.

Dandini, a Jesuit, was sent by Pope Clement VIII. in 1586, to ascertain the creed of the Maronites, resident on Mount Libanus, who had for some time professed subjection to the Roman pontiff, but whose sentiments were held somewhat inconsistent with the Catholic faith. The account of his mission was published in the Italian language, in 1656, translated into French in 1675, and into English in 1698. La Roque, in a French work published in 1722, gives a much more judicious and interesting description of the same country and people. His remarks on the ruins of Heliopolis, or Balbek, though not without value, have been superseded by the labours of Wood and Dawkins, two English travellers, to whom also we are indebted for the best observations on the remains of the ancient city of Palmyra, printed at London in 1753. Some errors in their description are said to be pointed out by M. Cassas, in his *Voyage Pittoresque de la Syrie*, &c. published a few years ago at Paris, with a preliminary dissertation by Volney, whose own travels through Syria and Egypt, in the years 1783, 84, and 85, of which we have an English translation, deserve particularly to be recommended to the reader's attention. Browne, in his travels in Africa, Egypt, and Syria, from 1792 to 1798, adds some particulars, but

Asia.

not of much importance. Savary, Wittman, Olivier, Griffiths, and Clarke, in their travels, occasionally treat of the same countries. Pococke's Description of the East, &c., is invaluable to the antiquary. The accounts of Palestine are numerous, but, if we except Hasselquist, are very defective in the department of natural history. The "Views, &c. from the original drawings of Luigi Mayer," published at London in 1804, "with an historical and descriptive account of the country," are of great value. Russel's work on the Natural History of Aleppo, and parts adjacent, has long been esteemed for its fidelity and minuteness of description as to manners and customs, &c. Drummond's Travels, London 1754, treat particularly of the Isle of Cyprus; but we have a still more valuable description by Mariti, written originally in Italian, but translated into English under the title "Mariti's Travels through Cyprus, Syria, and Palestine." Some additional information is to be found in Sonnini's Travels in Greece and Turkey.

2. Arabia. For this country, consult Salmon's Modern History, Lond. 1739.; Clayton's Journal from Cairo to mount Sinai, &c. Lond. 1753; Niebuhr's Travels through Arabia, Lond. 1799; Rooke's Travels to the coast of Arabia Felix, &c. Lond. 1783; Lord Valentia's Travels, &c. Niebuhr edited a work on the zoology of this country, after the death of its author, Forskal. It was printed at Copenhagen in Latin, under the title, "Descriptiones animalium, avium, &c. &c. in itinere Orientali observatorum."

3. Persia, including Armenia, Mingrelia, and Georgia, provinces to the north of that kingdom, under Turkish government.

The earliest work we shall notice is a Collection of Voyages and Travels in Persia, by Chardin, Lond. 1772. This is merely an extract, and is long subsequent to some French edition of Sir John Chardin's Travels, which have long and deservedly been esteemed, though the descriptions do not exactly correspond with present appearances, as ascertained by more modern observers. It is extraordinary that the great excellencies of this traveller have not prompted a competent person to give a better form to his work in our language than we now possess. Mr Harmer, author of Observations on various passages of Scripture, was favoured with the use of the MSS. of Sir John Chardin, by Sir Philip Musgrave, one of his descendants, to whom they were returned. But it does not appear that any farther advantage has been taken of them than what was requisite for Harmer's purpose. The works of Le Brun, Thevenot, Tavernier, and Hanway, may be occasionally consulted. Some information is given in Ives's Voyage from England to India in 1754, &c. Lond. 1773; Franklin's Observations made on a tour from Bengal to Persia, &c. Lond. 1790; and Forster's Journey from Bengal to England, &c. Lond. 1790 and 1798. The most recent accounts of this kingdom, &c. are Olivier's Travels in the Ottoman Empire, &c. Waring's Tour to Shiraz, Morier's Travels, Kinneir's Geographical Memoir of Persia.

4. India in general, and some of the countries in particular. We shall select a very few out of the immense number of works allotted to this portion of Asia, confining ourselves to recent times.

Grose's Travels to the East Indies, printed several times in London since 1759; Dow's History of Hindostan; Maurice's Modern History, &c.; Rennel's Memoir of a Map of Hindostan, Lond. 1788, &c. This is a work of great merit, and demands the attention of the geographer; Forrest's Voyage from Calcutta to the Bay of Bengal, &c. Lond. 1792, is of value as to hydrography; Hodge's Travels in India, Lond. 1793, give some good views of remarkable places; Campbell's Overland Journey to India, Lond. 1795; and Taylor's Travels from England to India, &c. in the year 1798, will be found instructive.

An Historical Account of the Settlement and Possession of Bombay by the English East India Company, Lond. 1781; Historical Fragments of the Mogul Empire, &c. Lond. 1782; Warren Hasting's Review and Memoirs of the State of Bengal, &c. Lond. 1784 and 86; Major Symes's Account of an Embassy to the Kingdom of Ava, in 1795, is extremely interesting; Barrow's Voyage to Cochin-China, &c. Lond. 1806; Dr Tennant's Indian Recreations; Forbes's Oriental Memoirs; the Asiatic Register, and Asiatic Researches; Turner's Account of Thibet; Kirkpatrick's Account of the Kingdom of Nepaul; Elphinstone's Account of the Kingdom of Cabul; Malcolm's Sketch of the Sikhs; Tytler's Considerations on India; Buchanan's Christian Researches; Hamilton's East India Gazetteer; all have strong claims to attention in the various topics to which they relate.

5. Indian Isles, &c. Percival's Account of Ceylon; Marsden's Account of Sumatra; Stavorinus's Voyage; Forrest's Voyage; Thunberg's Travels, Lond. 1794; Kæmpfer's History of Japan, translated into English, Lond. 1728; Oriental Navigator, Lond. 1801; Krusenstern's Voyage.

6. China, Corea, &c. Du Halde's General History, Lond. 1741; the Accounts of Lord Macartney's Embassy, particularly Sir George Staunton's Work, and Barrow's Travels; De Guignes's Voyages a Peking, &c. Paris 1805, has been highly commended.

7. Siberia, Kamtschatka, &c. or Asiatic Russia.

Voyage en Siberie, &c. par M. Gmelin en 1743; Pallas's Travels, translated into English; Clarke's Travels. For Kamtschatka, see last volume of Cook's last Voyage, and the works there referred to; also Coxe's Account of the Russian Discoveries.

ASILUS, THE HORNET FLY, a genus of insects, belonging to the order Diptera.

ASP, a species of serpent, arranged under the Linnæan genus *Coluber*, and which is supposed to be extremely poisonous. The indistinct characters which are applied to the asp, and the vague details which have been given of its dreadful effects, render it difficult to determine to what particular species they ought to be referred. But it can scarcely be doubted that the whole history of the asp, from the time of Cleopatra, who, weary of the world, exposed herself to the bite of this animal, to put an end to her miseries and her life, to the present day, is interwoven with the fabulous creation of credulity and ignorance; and nothing can afford a better proof of the advantages of precise definitions and accurate classification. The assertion that the poison of the asp produced death without pain, is too improbable to admit of a moment's belief.

ASPALATHUS, African Broom, a genus of plants belonging to the Diadelphia class. *Aspalathus Canariense* is supposed to be the species well known by the name of *Lignum Rhodium*, or Rosewood, from which the rich perfume called oil of Rhodium is obtained, as it is generally supposed, by distillation, although it may be doubted whether that singular and high-priced substance be really the product of that process.

ASPARAGUS, Sparrowgrass, or Sparagus, a species of plants belonging to the Hexandria class, of which the common asparagus is well known, and much cultivated on account of its shoots, which furnish the table with a rich delicacy.

ASPERIFOLIÆ, or Asperifoliate Plants, denoting such as have rough leaves, is one of the orders of the natural method of classification proposed by Linnæus. *Pulmonaria*, or lungwort, and *borago*, or borage, are examples of plants which come under this order.

ASPERUGO, Small Wild Bugloss, a genus of plants belonging to the Pentandria class.

ASPHALTITES, a lake of Palestine, which has been distinguished by various names, and described with much marvellous detail. The bitumen called asphaltum, which is a production of its shores or waters, is the origin of one of its names. From its situation and relative position it is called the *East sea*, the *sea of the Desart*, and *sea of the Plain*; the *sea of Sodom*, because it occupies the place of the three cities which perished for the wickedness of their inhabitants, with those of Sodom and Gomorrah; and the *Salt sea*, from its saline impregnation. These names are mentioned in Scripture. It is also denominated the *Dead sea*, from the notion which long prevailed that no animal could live in its waters, and that birds flying over it were suffocated by its exhalations, and dropped down dead. The more accurate observations of later travellers, and the analysis of its waters by the aid of modern chemistry, have furnished materials for its true history. The extent is indeed yet undetermined. It is variously described as 50, 60, and 100 miles long, and from 7 miles to 25 miles in breadth. The waters are quite transparent, and have a bitter and saline taste. The strong impregnation with earthy and alkaline salts adds greatly to their specific gravity, and accounts for the difficulty of immersion which those who have bathed in the lake experienced. Chateaubriand, a late French traveller, found it inhabited by numerous fishes, and swallows skim its surface unhurt in pursuit of insects. Mr Gordon, a Scottish traveller, took up a quantity of the water, and submitted it to the examination of Dr Marcet of London, who found its specific gravity to be 1.211; and 100 grains contained of muriate of lime 3.920, muriate of magnesia 10.246, muriate of soda 10.360, and sulphate of lime 0.054, the whole of which is nearly equal to one-fourth of the weight of the water in solid contents. The bituminous matter which is found floating on the surface of the lake probably derives its origin from the decomposition of mineral matters at the bottom, or some parts of its margin.

ASPHALTUM, or Jews pitch, an inflammable mineral substance which is found on the waters of the Dead sea in Palestine, and far more abundantly in the extensive *Tar lake* in the island of Trinidad in the West Indies. Se Mineralogy.

ASPHODELUS, Asphodel, or King's Spear, a genus of plants belonging to the Hexandria class.

ASPLENIUM, Ceterach, a genus of plants belonging to the Cryptogamia class.

ASS, a species of Equus. See Mammalia.

ASSAM, a country of Asia, which is bounded on the north by Thibet, on the west by Hindostan, and on the east by part of the Birman empire. All the vegetable productions of the warmer climates are abundant in this region; the soil in many places is strongly impregnated with nitre, of which, it is said, gunpowder is manufactured by the inhabitants; some gold is collected by washing the sand of the rivers; and some silver, lead, and iron are extracted from their ores. The natives of Assam are represented as almost entirely destitute of every moral and religious principle; but they possess a bold, fearless, and enterprising courage, which has enabled them to resist the most powerful attacks, and to preserve their independence.

ASSASSIN, a person who secretly puts another to death. The word is derived from the Arabic, which signifies *to kill*; and in the vulgar Arabic it denotes robbers in the night, or persons who lie in ambush to kill.

ASSASSINS, a tribe or race of people who occupied different regions in Persia and Syria, and were subject to a chief designated *the Old Man of the Mountain*, whose power was absolute. This race of people seems to have been actuated by the mixed influence of warlike and religious principles, combined with a barbarous heroism in the performance of deeds of the boldest enterprise. It is probable, too, that the chief of this ferocious banditti was employed by some of the powers of Europe as a horrid political instrument to execute vengeance on their hostile rivals, when open attack and ordinary warfare were unsuccessful; for when a victim was marked out for their revenge, a party was secretly dispatched to the place of his residence; with unceasing vigilance they observed all his motions; with unrelenting perseverance they pursued his steps, till a certain opportunity offered of inflicting the direful blow on his devoted head. For a period of 160 years these assassins continued to be the terror of Europe. Their numbers at one time was estimated at 40,000; and they were reduced and exterminated by the Mamelukes in the year 1280. See Hume's *Hist. of England*, and Gibbon's *Rom. History*.

ASSAULT is a law term which signifies an injury offered to a man's person. It has been defined an unlawful setting upon one's person, as when one person lifts his cane or fist in a threatening manner to another, or strikes at, but misses him. But what is termed assault and battery is constituted by an actual beating. See Blackstone's *Commentaries*.

ASSAYING is a process which is usually restricted to the examination of alloys of gold and silver, to ascertain the quantity of precious metal in the compound. See METALLURGY.

ASSER, JOHN, one of the earliest historians of Britain, is supposed to have been a native of Wales, assumed the monastic habit, and, on account of his learning, was warmly patronized by Alfred the Great. Several literary productions are ascribed, on doubtful authority, to Asser; but the *Annals* of the Life of Alfred, published by Parker in 1574, of which the latest edition was printed at Oxford in 1723, are supposed to be genuine. Through the influence of the learned Asser with the king, it is said that Alfred restored the university of Oxford.

ASSESSOR, is applied to a person who sits along with the judges in the inferior courts in Scotland, and with his professional knowledge assists in the decisions pronounced. Assessors are generally selected from the Faculty of Advocates.

ASSETS, an English law term which denotes the effects sufficient to discharge the burden which falls upon the heir or executor, in satisfying the debts and legacies of the testator or ancestor. Assets are either real or personal; to the first belong all lands which descend to the heir; and the personal estate or effects which go to executors are assets *personal*. See Blackstone's *Commentaries*.

ASSIGN, in the common law of England, signifies to make over a right to another, or appoint a deputy; but in a more restricted sense it signifies to set forth or point out, as to assign error, false judgement, &c.

ASSIGNATION, in the law of Scotland, denotes a deed of conveyance, by which the property of any subject which is not strictly feudal is transferred from one person to another. See Bell's *Dictionary of the Law of Scotland*.

ASSISE, from the French word *seated* or *established*, is a term of various signification in the law proceedings and domestic policy of this country: as the sittings of court; the regulations or ordinances of a court; a jury, because it sits till the verdict is pronounced; and the regulations of weights and measures, or prices of certain things, as the *assise* of bread.

ASSITHMENT, or ASSYTHMENT, a term in the law of Scotland, denoting a compensation, or *weregild*, by a pecuniary fine, which is due to the heirs of a person murdered by the person who is charged with the crime, and who pleads a remission.

ASSOCIATION *of ideas*, a phrase employed by logicians and metaphysicians, to denote that succession of thoughts which arise in the mind in consequence of some natural relation or accidental coincidence by which one idea or thought is called up by another in the mind, without any seeming exertion. Thus the scenes of early youth seldom fail to excite pleasing emotions; the occurrence of any of the incidents that accompanied a severe disaster, presents it to the recollection; the resemblance of a stranger in features, manners, or dress, recals the image of a distant friend; and this again by a new association, brings with it a train of agreeable reflections on his kindness, disinterestedness, or generosity. See LOGIC and METAPHYSICS.

ASSOCIATION, AFRICAN. See INSTITUTION.

ASSUMPSIT, is a term in the law of England which denotes a voluntary covenant or verbal promise, by which one person undertakes to perform or pay something to another. An assumpsit is either *express* or *implied*; *express*, when a positive and distinct agreement has been entered into; and *implied* where it may be fairly presumed, from the nature of the transaction, that such agreement was intended, or, according to the principles of equity, ought to have been made. See Blackstone's *Commentaries*.

ASSUMPTION, the capital of the province of Paraguay, in South America, stands on the eastern bank of the river Paraguay, and about 150 miles above the junction of that river with the Parana. It enjoys an agreeable climate, and the fertile soil of the surrounding country produces wheat, maize, sugar, tobacco, and cotton. The population exceeds 7000. The town can boast of little elegance; but it contains a cathedral, several churches, a college, and some convents.

ASSURANCE. See INSURANCE.

ASSYRIA, an ancient kingdom of Asia, which, it is supposed, comprehended the provinces of Diarbekir, Curdistan, and Irac. According to the older geographers, it was bounded on the north by Armenia, on the west by the Tigris, and on the east by Media. But its geographical limits are indistinctly known, and its civil history is involved in equal obscurity. Some notices of the kingdom of Assyria are recorded in sacred Scripture; and for an account of the conjectures of historians concerning it, see Rollin's *Ancient History*.

ASTARTE, and ASTAROTH, a Syrian or Phœnician goddess, called in Scripture the *Queen of Heaven*, and it is supposed is a divinity analogous to the Venus of the Greeks and Romans, the Mithra of the Persians, and the Isis of the Egyptians. Splendid temples were erected in honour of this goddess, and a train of three or four hundred priests was constantly occupied in offering sacrifices and oblations.

ASTER, STAR-WORT, a genus of plants belonging to the Syngenesia class, several species of which are well known ornaments in the flower-garden.

ASTERIAS, STAR-FISH, a genus of vermes belonging to the order *Mollusca*. See HELMINTHOLOGY.

ASTI, a city of Italy, finely situated in a valley on the banks of the Tanaro, adorned with an elegant cathedral, some fine churches, and many splendid public edifices, and including a population of more than 21,000. The surrounding territory is celebrated for its excellent wines.

ASTORGA, a city of the kingdom of Leon in Spain, which is surrounded with walls supposed to have been the work of the Romans. The population is estimated at 4000; and the distance from Madrid is about 150 miles.

ASTRACAN, an extensive province or viceroyalty of Russia, is bounded on the north by Bulgaria, on the south by the Caspian sea, on the west by the river Volga, and by a mountainous region on the east; and extends from the 46th to the 52d degree of north latitude. The summers are often extremely sultry, but the winters are sometimes very severe.

Wide tracts of this province are covered with saline marshes; but in many places the soil is fertile and produces a luxuriant vegetation, and some of the most delicious fruits. The vine thrives well; cotton is successfully cultivated, and the silk-worm is productive. The rivers abound with fish; and the fisheries are some of the chief sources of the wealth of the province. The manufactures of common salt, nitre, and leather, are extensive. Isinglass is prepared from the sounds or palates of the sturgeon and beluga; and caviare, which is transported to every part of Europe, is the salted roe of the same fish. The locusts are sometimes exceedingly destructive in this province.

ASTRACAN, the capital of the province of the same name in the Asiatic part of the Russian empire, stands on the banks of the Volga, which is three miles broad, and is the principal seat of the commerce of Russia in the east. A dockyard and naval storehouses have been established by the government to facilitate trade. The houses were formerly of wood, which rendered them liable to destructive fires; but stone and brick buildings are now more common. The population of Astracan is stated at 20,000; but the great resort of strangers from all parts of the world on commercial concerns, increases that number threefold. The established form of religion is that of the Greek church; but places of worship belonging to every sect and country are seen in the city. The central situation of Astracan commands a very extensive commerce, a large share of which is in the hands of Armenians.

ASTRAGAL, the moulding which separates the shaft of a column from the capital. See ARCHITECTURE.

ASTRAGALUS, Milk-vetch, or Liquorice-vetch, a genus of plants belonging to the Diadelphia class.

ASTRANTIA, Master-Wort, a genus of plants belonging to the Pentandria class.

ASTROLABE, an instrument employed by the ancients for making astronomical observations. This instrument resembled the armillary sphere. The same name is applied to other instruments for similar purposes, and particularly to one which was used for taking the altitude of the sun and stars at sea.

ASTROLOGY, a term originally and long synonymous with Astronomy, is now restricted to an imaginary and fictitious science, by which the future fortunes of individuals are supposed to be ascertained in the appearances, relations, and connexions of the heavenly bodies. It is a kind of divination which seems to have been practised seriously or fraudulently in the early stages of all nations; but the increase of knowledge, consequent on the improvement of social life, universally discloses its futility, and the revelation of the divine will supersedes its pretensions, and condemns its exercise. Wherever civilization, therefore, has attained stability, independent of the aid which superstition offers to the science of government; and wherever the Scriptures are freely allowed to modify public opinion, this delusive system is treated with contempt, and the influence and splendour which it may formerly have enjoyed are remembered with feelings of mortification and regret for the stupidity and weakness of mankind.

But unworthy and disgusting as it may be, the history of Astrology is a proper subject for philosophical investigation. Opinions so widely spread, and so strongly operative as those on which there is every reason to believe it was built must be deeply rooted in human nature. Their progress, supremacy, and decline, are intimately connected with the varying condition of our species.

What could give rise to the notion, that those immensely distant bodies which stud the firmament, and the inhabitants of this lower world, are so related, as that changes in the former are productive of, and foretel the vicissitudes of the latter? Different answers may be given to this curious question, but perhaps few of them deserve implicit, certainly none of them can demand exclusive credit. Probability is all that seems attainable in the discussion.

The coincidence of some remarkable event with an observed peculiarity in the arrangement of the celestial bodies, may have suggested the notion of their relationship. Several simultaneous occurrences of the kind would confirm it; for it may safely be asserted, that constancy of conjunction is one of the most imperative elements of natural logic. There are familiar examples in the universal reference of the transitions of day and night, and the returns of the seasons, not to mention the various kinds of weather, to the position of these bodies.

Again, the conviction, which is so congenial to our nature, and is so readily excited by the untoward circumstances of life, that there exists a power superior to human will and intelligence, may have been early coupled with the notion, that the heavenly bodies, especially the sun and moon, were the place of its residence, if not entitled, as was sometimes imagined, to the highest adoration. Hence would result the belief of the expediency and advantage of consulting their manifestations, as the primary causes and arbiters of all temporal concerns. In other words, this system may have originated in the conceits and absurdities of mythology, which again, it is probable, may be traced to the corruption of true religion.

A more refined sentiment, founded on the pride of man, and perhaps deducible also from a vitiated commentary on some divine revelation, might have held the elements of nature and the whole constitution of the heavens to be subservient to the necessities and comforts of our race, and therefore as well calculated to relieve anxiety for the future, as to minister to present demands. To this darling principle the stars might seem to share with some other things the office of pre-indicating events, and only from their greater dignity to be deserving of most attention. But this admission did not hold universally, as is evident from the preference given by some people to the entrails of animals, the flight of birds, the various kinds of oracles, &c.

Something similar to this last mentioned notion, is the belief, which is easily defended on a principle of piety, and therefore which was likely to be entertained wherever religion had a semblance of rationality, that the heavens and the earth being the creation of a beneficent and skilful architect, were in harmony with each other, and mutually indicated the revolutions which they were destined to undergo.

Astrology.

Of these, and it is believed all other solutions of the question yet suggested, it is obviously just to remark, that they rather point out the nature of the tendency to this system which exists in the human mind, than assign the grounds on which its peculiar principles and technical rules have been built. These it is impossible to explain, without entering more fully on the minutiæ of the pretended science than its importance demands, or the condition of physical and moral knowledge seems to require. Astrology appears to have found a favourable soil in the constitutions of Englishmen, as is pretty well proved by the number of treatises on the art which were published in the language, especially during the reign of queen Elizabeth. A complete catalogue of these works, with adequate notices of contents, is a desideratum, and merits the labour of one of our industrious antiquaries. The books themselves are never to be met with now, except in the libraries of collectors,—so much for the intelligence of our times. Several of them are mentioned by Sir Egerton Brydges, in his Censura Literaria and British Bibliographer. Moore's Almanack, the only *current* relic, it is believed, of a host of worthies, which used

> To deal in destiny's dark counsel,
> And sage opinions of the moon sell,

probably derives all its power of circulation from the sagacious adaptation of the kalendar, and other useful tables, to the stinted finances of the vulgar. The very general condemnation, it is thought proper to mention before concluding, of the *doubtful* sanction to the pretensions of the astrologer that is given in a recent novel, may be properly adduced as an evidence of modern incredulity. The sense of its absurdity must be powerful, indeed, which could reprobate a machinery, to use the language of criticism, defensible on the ground of poetic licence, and the source of such diversified excellencies and interest.

Astronium.

ASTRONIUM, a genus of plants belonging to the class Diœcia.

ASTRONOMY.

Definition.

ASTRONOMY is that branch of natural philosophy which treats of the heavenly bodies, and whose object is to discover the general laws which regulate their various changes.

The striking appearances of the heavenly bodies; the remarkable measures of time which they afford; the importance of a correct knowledge of their motions to the purposes of the arts; the scale also of these motions, which admits of their being estimated and expressed in sensible quantities, as lines and numbers, and thus allows us for the discovery of their laws the powerful aid of mathematical research, joined to the immense resources of art; all these causes have concurred in making Astronomy the oldest and most perfect of the sciences.

Arrangement.

In treating this subject, we shall, in Part I. consider the phenomena as they appear to the naked eye, and as every one can easily observe them. Having shewn how little information, concerning the system of the world, can be derived from this source, we shall in Part II. shortly explain the principles upon which more precise observations are made, and the results of these observations to the present time.

PART I. PHENOMENA OF THE HEAVENS AS THEY APPEAR TO THE NAKED EYE.

CHAP. I. OF THE PHENOMENA OF THE HEAVENS AND EARTH.

SECT. I. *Of the Diurnal Motion.*

Our notions of the phenomena of nature, which at first are always vague and indefinite, gradually improve as we continue our observations and reflections. The heavens and earth seem at first sight to form the two grand divisions of the universe—the earth a vast surface composed of sea and land, extending all around us; the heavens or the sky an immense roof or curtain, resting upon the earth at the extremity of our prospect, and extending over our heads.

The clouds which occasionally obscure this blue concavity, are often observed between us and terrestrial objects; we conclude that they cannot be far off, and belong rather to the earth than to the heavens: Our attention, however, is strongly attracted by the singular objects, the sun, the moon, and stars, which seem attached to the sky at a much greater distance, and which by considering them attentively we discover to be continually in motion.

The Sun.—The sun, by far the most striking object, is observed in the morning to *rise* out of the ocean, or from behind the most distant mountains—to traverse the sky at a considerable elevation,—and finally in the evening to disappear or *set* in the opposite quarter from which he rose, producing by this arrangement the vicissitudes of day and night. That quarter of the heavens in which he rises is called the *east*, the opposite quarter where he sets the *west*, and that line along the sea and land which seems to bound our prospect, and beyond which the sun seems to retire during the night, is called *the horizon.*

The Moon.—The moon, apparently equal to the sun in magnitude, though far inferior in splendour, follows the same course.

The Stars.—The stars have hardly any apparent magnitude; they shine like brilliant points in the sky, but their singular beauty, in a fine winter's evening, every one must have remarked with admiration. One curious circumstance regarding them, and of

Phenomena of the heavens, &c.

a character quite different from the setting of the sun and moon, is their gradual disappearance in the morning, before the approach of the sun. To discover the cause of this, observe the heavens a little after sun-set; the stars in the west are scarcely visible, while those in the east are shining with all their lustre. The same happens in a reverse order at the dawn of day; the stars in the east shine feebly, but those in the west exhibit nearly their usual brightness. It is natural to conclude that those luminous points are spread over the whole surface of the sky, and are only concealed from us during the day by the more dazzling light of the sun, and this conjecture has been verified by more precise observations.

So numerous and extensive a collection of moving objects, seems to present an ample field for such observations as may conduct us to a theory of the universe. We find, however, that, with a very few exceptions, a single motion appears to pervade the whole system. While these objects retain invariably the same positions relatively to each other, exhibiting constantly the same figures and the same groups which have even been recognised and designated from the remotest antiquity, and from which circumstance they have been termed the *fixed* stars,—while, in relation to each other, they thus exhibit every symptom of complete repose, we find that they have all a motion, whose direction a spectator can easily observe, if, on a clear night he take up some conspicuous position; and suppose he stands with the east on his left, and the west of course on his right, he will then have before him the *south*, and behind him the *north*, he will soon become sensible of the general motion. The stars in the west will be observed gradually to approach the horizon, and finally disappear, while new ones have, in the mean time, appeared above the horizon in the east; if, about the time of sun-set, he remarks some star in the east, near the point where the sun rose in the morning, he will see it follow in the very same course, rising to the same elevation in the sky, and approaching to the same point of the horizon in the west. The stars which rise farther before him in the east, or farther towards the south, will be observed to set farther before him on the west, and to mount to a less considerable elevation, exactly as the points of their rising and setting approach towards the south, or to the point directly before him. In fine, he will observe stars in the south which just graze the horizon, rising and setting in a very little time, and nearly at the same point.

If he now turn to the north, an arrangement somewhat analogous, but at the same time considerably different, will be remarked. Those stars which rise farther before him on the east, set also, as before, farther before him on the west, but they rise to a *greater* elevation in the sky. Some stars towards the north are observed to set, and almost immediately to reappear nearly at the same point of the horizon; but the most remarkable circumstance is, that some stars, as those of the constellation of the Great Bear, or the Plough, never set at all, but are visible during the whole of the night; and that there is a point considerably elevated above the horizon, where the stars seem in perfect repose, and round which the former, as they are observed sometimes above, sometimes below, sometimes east, and sometimes west, but always at the same distance from it, round which, therefore, they seem to describe circles larger and larger as their distance from it increases. In short, all these appearances are exactly what would happen, by supposing the whole heavenly bodies attached to the surface of an immense sphere, quite unconnected with the earth, but of which the earth occupies the centre, and revolving upon two fixed points diametrically opposite to each other, of which the one is that point considerably elevated above the horizon, where the stars are observed in repose, and the other is concealed from us by the horizon being equally depressed below it. Thus, let P H p O, Plate 21. Fig. 1. represent a globe or sphere turning upon two points, P, p; or join P p, turning upon an axis, P A p, and let the lines, *a b c*, *a b c*, &c. (which are conceived to rise above the paper, from *a* and *c* to the centre *b*) represent the circles which the points, *a a*, &c. describe, by revolving always at the same distance round the axis P p, increasing in magnitude as they recede from the stationary points, P, p. Let a spectator now on the earth at the centre A, and whose horizon is H A O, view the stars in the hemisphere H P O revolving in the direction E A Q, H will be the south point of the horizon, and O the north, P will be the point where the stars seem at rest, and round which they seem to circulate in larger and larger orbs, *a b c*, 1 b 2, &c. as they are situated farther and farther from it. At the point c, in the circle 1 b 2, the stars will be observed to set, and in a very little time to reappear nearly at the same point; at the point H, they will just seem to graze the horizon; and in proportion as their points of rising and setting, *e*, *f*, &c. are situated farther and farther from H, they will rise to a greater elevation H g, H r.

It is natural to conclude, from all these appearances, that, could we see below the horizon, the stars would appear to move in a manner perfectly similar to what we remark above; and that another pivot would there be observed, round which their revolutions would seem to be performed.

Horizon.—What, then, is the nature of the horizon, which hides so many objects from our view? The answer to this question may perhaps be obtained, by changing our situation on the earth, in the same manner as we find the distance of remote objects by viewing them from different positions. We shall thus see what becomes of the apparent barrier of our prospect, by continually advancing towards it. The aspect both of the heavens and earth is accordingly observed to change continually as we change our point of view. On the earth we lose sight of some countries and discover others; by advancing towards the south, we discover, on looking to the south, stars, just appearing above the horizon, which had not formerly been observed, while those that formerly grazed the horizon are now observed to rise more and more above it, as we continue to advance more and more to the south. On looking again to those stars in the north, which had formerly never set, but which, in the inferior part of their course, came very near the horizon, we find that they now disappear for a short time;

and reappear nearly at the same point, while those which we had formerly observed so short a time below the horizon, now continue invisible longer and longer as we advance to the south. It is apparent, then, that the horizon, instead of being a real limit, is receding from us on the one hand, and thus discovering to us new objects, while it is following us on the other, and hiding from us those objects which we had formerly observed. By advancing in this manner, the same appearances continue, till we at last discover a point in the southern sky where the stars seem again in complete repose, and whose existence our previous observations had indicated with considerable probability.

Celestial sphere.—The sky and the stars, then, are no where coincident with the earth, as we at first imagined; in fact, to whatever part of it we go, they seem always at the same distance from us; they seem, therefore, evidently to be arranged upon the surface of an immense sphere, of which we ourselves occupy the centre. This is called the *celestial sphere*; it is not a real object, it is merely a conception of the figure that would seem to arise from the junction of all the stars by some material substance.

We may consider it, therefore, as an established fact, that the system of the stars on the celestial sphere seems to revolve once every day round two fixed points. This motion is called the *diurnal motion* of the sphere or of the stars, and the fixed points are called the *poles* of the sphere; the one which we observe in this country is the North, the other the South Pole; and an imaginary line joining the two poles, is called the *axis* of the sphere.

Figure of the earth.—Let us now attend to the singular figure which these appearances should lead us to ascribe to the earth. The figure of the surface which in any case bounds our prospect, is always indicated by the manner in which new objects make their appearance as we change our situation. In a flat country, the view is much less varied than in one that is more irregular; in the one the traveller observes nearly the same objects from every part of it; in the other, where he sometimes descends into valleys, and sometimes ascends to considerable elevations, he is continually losing and regaining his view of the distant landscape. On attaining the summit of some great mountain, the whole country on the opposite side often bursts upon him at once, while in other cases it rises into view always the more gradually as the curvature of the mountain is less abrupt.

Its roundness.—Advancing upon the earth, then, on a much greater scale, since we are continually discovering new objects, its figure cannot be that of an immense plain, as we are at first so strongly tempted to imagine, while the regularity with which the stars in the north disappear as we advance to the south, and those in the south become visible, evidently indicates, upon the whole, notwithstanding its apparently immense irregularities, a degree of roundness, or regular curvature, in the direction of north and south, like that of a swelling eminence, on which the spectator, as he advances, gradually discovers the country before him, and loses sight of that which is behind. We thus appear to be in the situation of a person on the curved surface A B C D, Plate 21. Fig. 2. viewing the stars in the hemisphere H P O p, the surface being so immense, in respect to himself, that he can see but a very small portion of it all round him at a time; and that the line H A O, which touches it at the point where he stands, and therefore changes its direction along with him, forms nearly the boundary of his prospect all round, and prevents him from seeing more than one portion, HPO, of the sphere H p o at a time; when he arrives, therefore, at B, this horizon has assumed the position h B o, discovering to him the stars in the portion H h, and hiding those within O o. But this convexity of the earth, is far more strikingly manifested by observations on the smooth surface of the ocean. When navigators recede from the shore, they observe the edifices and mountains gradually sink, and finally disappear; while the vessel presents the same phenomena to the spectators on shore, gradually sinking, and, finally, like the setting sun, plunging into the ocean. This cannot be owing to the distance, which tends to make objects appear less, as a small object becomes invisible upon a distant mountain; for the mariner, by ascending to the top of the mast, sees distinctly those objects which had disappeared to him upon deck; while the vessel re-appears to a spectator on the shore as he mounts to a greater elevation.

Circumnavigation.—But the most decisive proof of the roundness of the earth, is its actual circumnavigation. This bold attempt was first made by Magellan. Setting out from one of the ports of Portugal, he advanced in a westerly direction, and, after a long voyage, arrived at the great continent of America, already discovered by preceding navigators. Unable now to continue his route towards the west, he sailed along the coast to its southern extremity, and passing the straits known by his name, found himself in an immense ocean, already known by the name of the South Sea. Resuming now his course westerly, Magellan arrived at the Molucca islands, where he lost his life; and his vessel, still proceeding westward, finally arrived at Europe, and entered, as if from the east, the port it had left for the west. This great experiment has been often repeated; and it clearly shews the earth to be convex from east to west, as we have already observed its roundness from north to south.

Antipodes.—It is curious, no doubt, to consider, that those who inhabit different parts of the earth have their heads turned different ways, as in Fig. 2.; and it might be at first imagined, that those who are opposite to us would fall off the earth on account of their own weight; but if weight be considered what it really is,—a tendency which all bodies have to descend in straight lines directed towards the centre of the earth, its direction must evidently vary like the spokes of a wheel; and the same force which attaches us to the earth, will, acting in an opposite direction, attach our *antipodes* to it in the same manner.

However strange, therefore, the conclusion is no less irresistible, that *the land and waters of our earth compose a mass round in every direction and insulated in space.* It has been found to exceed 8000 miles in diameter, or to be nearly 25,000 miles in circumference.

It is certainly difficult to conceive, how the earth, thus apparently unconnected, can support itself in the middle of space; for we naturally extend to the earth itself the property of weight, which we observe common to all the bodies on its surface. But admitting that the earth actually has a tendency to descend to some portion of space, it is not impossible for it to be at the same time endowed with a tendency, in another, perhaps an opposite direction, so as to remain suspended by the combined effect of the two forces, like a balloon, under the joint influence of gravity on the one hand, and its own buoyancy on the other; or there may be various ways in which nature might produce the same effect. As there is nothing, therefore, in the phenomenon of weight inconsistent with the earth's remaining suspended, instead of doubting, on this account, a fact which all our observations so remarkably confirm, astronomers have rather inquired the more diligently into its cause; and its developement has disclosed the true system of the world.

Sect. III. *Dimensions of the Celestial Sphere.*

Let us now endeavour to obtain some idea of the distance of the stars, or of the sphere whose centre we seem to occupy. This attempt, though at first it seem difficult, if not impracticable, is effected upon very simple principles. But there are two kinds of distance, which must never be confounded in astronomy, and of which, as it is very simple in itself, we shall here explain the distinction; the one is *linear*, the other *angular* distance.

Linear and angular distance.—Let there be a series of objects, A, B, C, D, Fig. 3. situated in the same line A B C D; they will mark out larger and larger portions of linear extent A B, A C, A D, &c.; and to a person at A, his distances from B C D, &c. always mean the lines A B, A C, A D, &c. But, viewed from the point *a*, the objects will mark out at the same time larger and larger *angles*, A *a* B, A *a* C, &c. and the distance of the two, A and B, relatively to a spectator at *a*, means their angular distance; it is the angle which the lines converging from the objects to the eye, or diverging from the eye to the objects; the angle or degree of opening or divergence which these lines, a A, a B form at the eye, or the direction of one of the objects relatively to the other.

The same will happen, if, instead of a series of objects, a single object be supposed to assume successively the positions B C D, &c.; and if a continued motion be ascribed to it in the line A B C D, it will then mark out every possible degree of linear extent, as it continues for ever to recede from the point A. To a spectator at *a*, however, it will by no means mark out all the degrees of angular magnitude; for at the greatest distance, suppose *n*, to which it can possibly arrive in the line A B C D, the angle A *a n*, however near it may approach, can never actually attain, far less exceed, the magnitude of the angle A *a y*; *a y* being the limiting direction to which the line *a* A, *a* B, *a n*, joining the object and the spectator, is continually approaching as the object recedes from A, but to which it can never actually arrive.

It is only when the object is supposed to change its direction, so as to revolve round the spectator, that it exhibits every variety of angular distance. The line A *a* will, in that case, revolve about its extremity, *a*, and will go on for ever to describe new portions of angular extent, reproducing, however, after a complete revolution, the very same series of changes in position; after revolving from A *a* to A *y*, and to A *a* again, it will just recommence the same course, occupying in succession the same identical situations *a* B, *a* C, *a* D, as well as all the intermediate points.

The whole circuit, then, becomes a fixed and very convenient standard for comparing one degree of divergence with another. Its fourth part is called a *right angle*. Thus, when the line a A, Fig. 4. having made a quarter of a revolution, comes into the position a B, the angle A a B is called a right angle; the lines a A, a B are said to be perpendicular to each other; or if they form the two sides of a solid body, A a B, Fig. 5. it is said to be *square* at the point a. When a A, Fig. 4. has described the next quarter revolution, being now in the position a C, directly opposite to its first position a A, and having thus described half a revolution, or two right angles, it then begins to approach its first position, though the angles reckoned in the same direction are still increasing. When it arrives at a D, it has described three right angles, or three quarters of a circuit, though it now only wants one from its first position. Any line, a Z, situated between a A and a B, diverges less from a A than a B, and any line, a Y, between a B and a C, more; A a Z is less than a right angle, it is an *acute* angle, and A a Y greater, it is an *obtuse* angle. See *Leslie's Geometry*.

Though there is, in reality, therefore, no difference in the manner in which an object changes its position, yet, relatively, to the position of a spectator, there thus arise two kinds of distance, which are exhibited, uncombined with each other, linear by a *progressive*, and angular distance by a *revolving* motion. These two sorts of distance are quite independent of each other; for as the distances A B, A C, AD, Fig. 3. of the progressive point would have been the same in any other line, A b c d,—as, in estimating its distance, it is of no consequence to a spectator at A, whether the point goes off towards the north, south, east, or west,—as the linear distances of objects are therefore no way affected by their direction, neither are their angular distances any way affected by their remoteness. Provided two objects be situated, the one on the line a B, Fig. 4. the other on the line a A, though the one be 10, 100, or 1000 miles farther from the point A than the other, their angular distance is still represented by the angle A a B; and on the other hand an object may shift to every point of the compass without ever changing its distance from the centre of motion.

But progressive motion becomes much sooner insensible to us as the object recedesto a distance than angular. We are often at a loss for some time to determine whether a vessel, far out at sea, is advancing, stationary, or retiring; while another, at the same distance, and having really no greater velocity, is making a sensible progress to the right or left. It is thus with the heavenly bodies; their distances from us are so great, that their progressive motions, if they have any, are to the naked eye altogether in-

Phenomena of the heavens, &c.

sensible, while their angular or revolving motions are obvious to the most careless observer; hence it is to the latter that we look, in the first instance, for any information as to the system of the world; and hence the term distance in astronomy refers much more frequently to angular than to linear distance.

Measurement of distance.—When objects are near us, we form, at a glance, a pretty correct estimate of their distance; but this rapidity of conception arises from experience, aided by the wonderful power of habit. It is well known, that when a person, blind from his infancy, suddenly acquires the use of his sight, he has no idea whatever either of the position or the figure of surrounding objects, either of their angular or linear distance. He has got possession of a new and very powerful instrument, but is utterly at a loss how to manage it. His ideas seem to be all formed upon the scale of his sense of feeling. In the case of a young man, couched by Cheselden, all objects, it is said, seemed to touch his eyes as they had formerly affected him by touching his skin; he still was unable, by his sight alone, to distinguish a round from a square body; in short all seemed confusion and perplexity before him, and it was only by continually comparing the impressions of his feeling with those of his sight, that he was trained to the use of his new sense.

Even with those, therefore, whose vision is perfect, as might be expected, this faculty of distinguishing distance at sight declines rapidly, as we lose the power of measuring the impressions of the one sense by those of the other, either when the objects become more and more remote, or when fewer of them intervene, whose distances can be compared with the extreme one. It is on this account that we are so much less sensible of distance at sea, where there are few intervening objects, than at land, where there are houses, trees, and a variety of objects whose distances can be compared with each other, and with the remote one. It is thus also that the heavenly bodies, on account of their remoteness, seem to us all at the same distance; but we must not infer like the blind person above mentioned, that this is really the case; for any thing we know to the contrary, some of them may be immensely farther off than others; and analogy is rather in favour of this supposition. Experience and observation only can give us any idea of their real distances.

Accessible objects.—When the objects, whose distances we would discover, are accessible, we supply the defect of our sight by measuring from the one to the other; by finding, for example, how often a chain of 100 feet must be repeated, in order to extend from the one to the other; and in this we only perform the same process of comparison experimentally, which we had formerly carried on rudely in the mind.

Inaccessible objects.—When the objects are inaccessible, or where the route between them is any way impeded by the nature of the ground, this species of measurement is impossible; and here, therefore, our power of finding linear distance seems at first sight to terminate. But this is by no means the case; for as we have seen that angular motion is much more sensible to us than progressive motion, so our faculty of distinguishing distance is much more acute in the case of angular than of linear distance. This property of the former greatly extends our power of estimating the latter, and the distance of an inaccessible object, can always be determined within certain limits, by finding its direction from different points of view.

Every one must have observed, that, when he changes his situation upon the earth, the surrounding objects change their bearings with regard to him; they are referred to different quarters of the sky. Let a spectator at A, Fig. 6, observe the object O at the distance of a mile, bearing due west; let him now advance a mile towards the north to B, and the object will also appear to have advanced towards the south, and to have come into the direction B O C, exactly south west. It may also have been remarked, that when the object is distant, the change in its bearing corresponding to the same change in our situation is much smaller than when it is near. Suppose the object O, bearing west, is two miles off, or that the spectator is at A′, and let him here advance a mile towards the north to B′; the object will now appear in the direction B′ O C′, not nearly so much southward as at first. In the same manner, had the object been three, four, or more miles off, the spectator at *a a*′, by advancing a mile northwards, would observe a smaller and smaller change in its position. It is thus that we estimate the distance of remote objects; we change our own position, and mark the corresponding change in theirs. This principle applies with peculiar facility to the case of a number of objects like the fixed stars, situated as they probably are at different distances from the spectator.

Thus, suppose that there is a collection of objects, 1, 2, 3, 4, &c. Fig. 7. so far from the spectator at A, that their various distances from him become confounded in the common distance of a sphere C D, on whose surface he imagines them all to be placed, and of which he himself occupies the centre. Now though the objects are really disposed in a manner quite irregular, yet to the person at A they will seem to be arranged at equal distances, by threes, on the sphere C D. Let him view them from a different position, B, Fig. 8. to the right of A, and they will now seem to have arranged themselves by twos on the sphere C′ D′, of which B is the centre. Again, at the point *b*, they will appear without any order on the sphere *c d*. Let him now assume three new positions A B b, Fig. 9. much farther off, but equally distant from each other, and much less difference (hardly any indeed) will be observed in their arrangement upon the spheres C D, C′ D′, and *c d*. By observing the objects from positions still more distant, a proportionally smaller change will be remarked in the aspects which they present; and when at last the change becomes altogether insensible, we may be assured that the distance of even the nearest of the objects is out of all proportion to that of the extreme positions A B.

Distance of the stars.—But to whatever part of the earth we go, the fixed stars preserve constantly their mutual order and arrangement. We conclude, then, with certainty, from this simple observation, that their distance is out of all proportion to any that

Phenomena of the heavens, &c.

we can go upon the earth, and that in relation to it therefore the earth itself, which we at first imagined the principal part of the universe, must be considered as a mere point.

Sect. IV. *System of the World.*

From all that has been observed, it appears that Fig. 2. is a correct representation of the universe, where A B C D is the earth, and P H p the celestial sphere, with the sun, moon, and stars revolving once a-day from east to west, round the poles P p, or round the imaginary axis P p, which passes through the centre of the earth; the sphere being placed at an immensely greater distance in relation to A B C D.

In a system of bodies revolving round a centre in the same time, those that are more distant must obviously have a greater velocity than those near the centre. By the revolution of the celestial sphere, then, each star must have a velocity peculiar to itself, greater as it is more distant from the nearest pole, or from the axis of revolution, greater at *e* than at *c*, and greatest at the points E Q, intermediate between the two poles, where, as we have found the distance to be so immense, so the velocity necessary to make the stars in the circle, E Q, complete their circuit in a day, must be equally astonishing.

The stars are apparently quite unconnected with each other. If we admit their diurnal motion, therefore, it would follow as a necessary consequence, that these objects moving, some slow, some quick, and some with a rapidity beyond all conception, have at the same time their velocities so nicely adjusted, that each of them completes, with wonderful regularity, a revolution every day round the earth, which we have discovered to be a mere point in the system of nature. To obviate this difficulty, it was supposed by some astronomers, that the stars were really attached to an immense crystalline sphere, and that all their motions were to be ascribed to the daily revolution of this huge body of glass.

Motion of the earth.—Another hypothesis, however, of much greater simplicity and elegance, explains equally well the phenomena, though it is at first strongly opposed by the prejudices of our senses. This hypothesis converts the apparent motion of the stars, into a real motion of the earth round itself, in a contrary direction, in such a manner that its axis of rotation, P′p′, Fig. 2. points to the celestial poles, or coincides with the celestial axis. The appearances will evidently be the same whether we attribute the motion to the one or the other, whether we suppose the portions of the celestial sphere to be brought successively over our heads, or ourselves to be carried successively under them, by the effect of the earth's rotation, in a contrary direction. Let a spectator at A, Fig. 10. view the stars *a b c d*, and the moon M; *a* just rising above the horison H A O; *b* towards the east, and considerably elevated; *c* directly over his head, and *d* towards the west; let him view them again in a short time, and he will observe that they have all made an advance towards the west, as in Fig. 11. Now, it is obviously the same to the spectator whether these bodies have been actually carried into their new position, along with the sphere *a b c d*, as in Fig. 11. or he himself has been carried, by the earth's rotation, from west to east to the point A′, Fig. 12. and his horizon with the point directly over his head to the position H′A′O′ and *c*; whether the one or the other of these events has happened, he will still see, at the second observation, the star *a* and the moon at the same elevation, *b* directly over his head, and *d* in the horizon. Since the appearances are absolutely the same then in either case, let us see to what objections the latter is liable from other quarters.

We have frequent examples of such a motion. A ball tossed from the hand, while it rises into the air, turns at the same time round itself—or round an imaginary line passing through its centre, and termed *its axis*. Observe also the tops with which boys amuse themselves; while they advance by continued impulsions, they have at the same time a rapid rotation round their points.

But however agreeable to nature, it still requires no little effort to credit the existence of a motion to which we ourselves are subject, which remained unknown for ages, and of which we are even now altogether insensible. Observe, then, what happens to every one who is thus carried along by some external impulse. In sailing close along the coast, and in smooth water, while we remain in the cabin, and see no external object, we are utterly ignorant whether the vessel is going quickly or slowly, or whether indeed it has any motion at all. But, when we come upon deck, we instantly perceive an apparent motion in all the external objects, which experience and habit have taught us belong to the vessel, but which, on our first viewing the phenomenon, we would infallibly have ascribed to the objects, as it is even yet often difficult to resist the illusion. Without experience, indeed, we could have no reason whatever to refer the motion to the one more than to the other, except perhaps its being simpler in one than in a variety of objects no way connected together. So it must happen to us on the earth; whatever motion it may have, provided all the objects around us participate in it, and we ourselves participate in it, we are no more sensible of it than if it had no existence. But when we look beyond the earth, and observe a motion common to all the external objects, the sun, the moon, and the stars, we can have no reason whatever for ascribing it to the objects rather than to the earth, while analogy and a regard for simplicity are in favour of the latter hypothesis. The question, however, can only be decided by more continued observation and reflection. In the mean time, we shall continue to speak of this motion as belonging to the stars.

Chap. II. Phenomena of the Sun and Moon.

Let us now consider more particularly the Sun and Moon. These bodies seem far to surpass the stars in magnitude and brightness, and it is easy to observe, that they are equally distinguished by motions peculiar to themselves.

Sect. I. *Of their Distance, Figure, and Magnitude.*

We cannot, by merely viewing these objects, form

Phenomena of the sun and moon.

any idea of their distance, and, therefore, the one may be much farther off than the other; but their superior magnitude and brightness,—the striking effects which they produce upon the earth,—and their peculiar, or *proper* motions, as they are termed, might all incline us to place them both nearer to us than the stars. What are we to think of their figure and magnitude? Like our earth, they are insulated in space; and though they appear like thin plates, the one of fire, the other of pale light, we must not infer from this that they have really no thickness. There is hardly such a thing on earth, if it be not the productions of art, as an object without a thickness in some degree proportioned to its length and breadth. All spherical bodies, besides, present the same appearance when sufficiently remote. As the sun and moon, therefore, would have exactly the same appearance though we should ascribe to them, like our own globe, a roundness in every direction, it is natural to adopt this supposition, which analogy points out, and to try it by future observations.

Though the sun and moon seem so small in respect to the objects around us, their real magnitudes may be very great; as the hugest man of war, on the distant horizon, appears no bigger than a boat, or as a person at a great elevation observes all the inferior objects on a reduced scale. Thus, to a spectator at A, Fig. 13. the object C D seems smaller and smaller as its distance increases; so that we have no idea, at sight, of the real magnitudes of distant objects.

Of near objects we can no doubt form at once a pretty correct estimate of the real size; and we would think it strange in a person to suppose an object any larger, because, on being brought closer to his eye, it occupies nearly the whole field of his view. This, however, arises entirely from our habit of distinguishing distance at sight. The blind person couched by Cheselden, when a small object, perhaps only an inch square, was placed before his eyes, so as to conceal from him a large house, found it impossible to conceive at first how the house could be any larger than the object, or the object any smaller than the house. It is the same with us when we look at the sun and moon. We are entirely ignorant of their distances; and the deception as to their real magnitudes is equally complete. For aught we know to the contrary, therefore, they may equal, or even surpass in bulk our own globe itself.

The sun and moon appear much fainter and larger in the horizon than when a little elevated. The faintness is principally owing to the fogs and vapours that are generally spread through the air in the horizon, and in passing through which the light of those bodies is considerably interrupted. Their greater apparent magnitude in the one case than in the other is generally ascribed to our imagining them at a greater distance in the horizon, where houses, trees, mountains, and other objects intervene, all whose distances we know and can compare with that of the sun or moon, than in the sky, where no objects intervene, and where we, therefore, imagine them much nearer us than before. To be convinced that it is an illusion, it is only necessary to observe the sun or moon through a tube small enough to admit in its field of view only the moon itself, or through a small hole in a piece of paper, or through a glass so smoked, that, by placing the eye close to the glass the moon only can be seen; it then appears of the same magnitude in both cases.

Sect. II. *Of the Moon.*

The motions of the moon are the most remarkable, both for their rapidity, and for the singular changes of her shape with which they are accompanied. She is sometimes observed towards the east of the sun, sometimes towards the west, and sometimes directly opposite to the sun. Sometimes, again, she assumes the form of a whole circle of light, sometimes a half circle, sometimes a slender crescent, and sometimes disappears entirely from the heavens. But as we are continually losing sight of terrestrial objects when other objects intervene, or when the light that is necessary to perceive them is withdrawn, as when a vessel at sea disappears behind some island, and reappears in a short time on the opposite side, or when the whole sky is obscured by clouds, or when all the objects in a room disappear upon extinguishing the candle; it is natural, therefore, to ascribe the moon's disappearance to the effect of some such circumstance. A close attention to her motions may unfold the true cause.

Her proper motion.—If the moon be observed attentively when a little westward of some brilliant star, it will be perceived, in the course of the night, that though they are both making advances towards the west, the moon is at the same time gradually approaching the star, to which at last she arrives; the star disappears behind her, and in a little time emerges on the opposite side, exactly as happens when an opaque or untransparent body coming between us hides the distant objects. Next evening the star will be observed considerably westward of the moon.

Either, then, the moon has in reality a slower motion from east to west than the stars, or she participates equally with them in the diurnal motion, while she has, at the same time, a contrary and a slower motion from west to east peculiar to herself, by virtue of which she falls behind in the general motion. The appearances are the same in either case; for when we observe the moon to-night at M, Fig. 14. west of the star S, and to-morrow night at the same hour at m, east of the star S, the effect is evidently the same, whether we ascribe to M a single motion from west to east, which in the course of 24 hours would carry her over the arc M O C H m, while the star is carried, by the diurnal motion, all the way round from S to S again, or that we suppose m actuated in common with the star by the diurnal motion, which would carry her in 24 hours all the way round from m to m again; but that she has, at the same time, a contrary motion of her own, which in 24 hours carries her over the arc M m from west to east. As this last is what would certainly happen by ascribing the diurnal motion to the earth, and not to the stars, therefore, till further experience decide the question, we shall speak of it in this way, and suppose the moon to partake of the general motion of all the stars from east to west, (from the left to the right, when one looks to the south,) while she

Phenomena of the sun and moon.

has a motion of her own in a contrary direction from west to east, called her *proper* motion.

Sometimes the moon rises nearly at the same point of the horizon where the sun had risen in the morning, and follows him nearly through the same arc of the heavens to the horizon again; sometimes she rises much farther to the south, and sometimes much farther to the north of this point, mounting respectively to a less or more considerable elevation, and setting also farther to the south or north. In following the series of her *phases*, we shall, for the sake of simplicity, suppose her to remain in the same circle of the sphere *a b c d*, Pl. 24. Fig. 1. with the sun.

Phases.—The moon's changes of figure and situation are soon discovered to be successive, and closely connected together. At the time of *new moon*, when she first reappears in the sky, under the form of a slender crescent, after having been invisible for a few days, it is always in the evening towards the west, but eastward of the sun, the horns of the crescent also pointing to the east nearly as at *a*, the sun, S, being in the horizon H O.

Each succeeding evening, when the diurnal motion has brought the sun to the horizon, the moon appears to be farther and farther (we mean here obviously her angular distance) from the horizon, and from the sun; to set later and later after the sun; and to be thus making continual advances towards the east. Her size also is at the same time observed to increase, the concavity of the crescent gradually filling up, the horns becoming less and less pointed, and the whole figure merging into a semicircle as she approaches the position *b*, which she attains in a few days, having overtaken and eclipsed in her passage the bright star S.

It is then *half moon*, or she is said to be in her *first quarter*. But the same appearances continue for another week, till she arrives at a point *d* opposite to the sun, having successively assumed all the intermediate angular positions from *b* to *d*, and all the intermediate figures from the half to the whole circle.

It is now *full moon*, or she is now said to be *in opposition*. She now rises at sun-set, and sets at sun-rise, and shines through the whole of the night. But as she is now at her greatest distance from the sun, for she evidently cannot advance farther in her circle of revolution, *a b c d*, without approaching the sun; and as her shape is now also complete; as these changes of situation and figure have both attained their *maximum*,—they now begin to run in a contrary direction, and all the preceding phenomena to occur in a reverse order.

Each succeeding evening the moon rises later and later after the sun; or, if the observation be made in the morning, she appears in the west at sun-rise, and farther above the horizon every day, and still, therefore, advancing towards the east, but now approaching the sun, as in Pl. 24. Fig. 2. When, in the course of another week, she comes to the position *f*, Fig. 1. or Fig. 2. her figure being now reduced to a semicircle, it is again *half-moon*, or she is said to enter her last quarter. Her figure now decreases in approaching, as it had formerly increased in receding from the sun; her horns, at the same time, pointing towards the west, as they had formerly done towards the east, in both cases *from* the sun. In the course of a few days we cease to perceive her at all; and it can hardly be doubted that it is the same identical object which in a few days more makes its appearance in the evening to the east of the sun; having, in the mean time, just performed, though invisible to us, the remaining and intermediate series of her changes of position from *g* to *a*, and of figure from the crescent to the crescent again, after a period of complete evanescence at the position *h*, being then, at the same time, neither east nor west of the sun, her angular distance, therefore, having also become nothing. This is the *change* of the moon; and having now attained the *minimum* of her changes, she just recommences the same series.

The period of all these phases is about 29 days and a half, and is called *a lunar or synodical month*, or simply a month. It is the interval that elapses between two successive new moons, or two successive changes, or between two successive arrivals of the moon, at her first or last quarters.

Whatever, then, be the nature of her changes of figure, the moon seems evidently to describe a circle in the heavens, in going from west to east, from the sun to the sun again, once in a month, rising all the time in the east, and setting in the west, every day.

It very rarely happens that the moon, when she comes into the position *h*, being then neither east nor west of the sun, is at the same time (as we have supposed in the figure) neither north nor south. By observing the points of her rising and setting before and after her entire disappearance, we find that, at the change, she is most frequently more or less either to the north or south of the sun, (either a little above or below the paper in the figure.)

But though it is very seldom that these bodies are exactly in the same direction, yet as we have found them to be in a position, at *h*, neither east nor west of each other, once every month, the one being at that time more or less north or south of the other, (above or below the paper;) and as it is observed that they are also, once every month, neither north nor south of each other, being at that time the one more or less east or west of the other; as these two conditions thus occur separately once every month, it is certain that, in the course of ages, they will be united at one time, and the sun and moon will occupy the same angular position.

In that case it is plain, that were the sun and moon at the same time equally distant from the earth, they would both occupy the same identical portion of space; this is impossible, if, as is probably the case, they are composed of solid matter, like our earth; there would then infallibly arise a collision between them, and a consequent derangement of the moon's motions. But as this never happens, it is more natural to conclude, that the moon passes either beyond or between us and the sun. In the latter case, were the moon composed of opaque or untransparent matter, like our earth, it is certain, that, coming so directly between us, she would hide the sun from our view, as when we pass an object between us and the candle; she might then spread total darkness over the earth, and so remarkable a phenomenon

Phenomena the sun and moon.

would undoubtedly be recorded either in history or tradition.

Eclipses of the sun.—But it is well known that we have the most authentic accounts of *total eclipses of the sun*, which, in ignorant ages, were regarded with terror. In these phenomena, the western border of the sun, which first disappears, is also the first to re-appear, as he successively assumes the figures 1, 2, 3, &c. Pl. 21. Fig. 3. exactly as would happen by a round opaque body passing between from west to east.

Partial eclipses of the sun, of various extent, are also observed, on some part of the earth, every year, in the middle of which the sun assumes all the forms, 1, 2, 3, &c. Fig. 3. Sometimes, too, at the middle of the eclipse, the whole opaque body is observed like a large spot in the sun, whose exterior border projects all round like a ring, Fig. 4. This is called an *annular* eclipse.

Now, it is certainly much less agreeable to any thing hitherto observed, to suppose that the sun really loses and recovers his light by some internal arrangement, of which we can give no sort of account, than to admit the most common fact of an opaque body shading an enlightened one. And as we can discover no body in the system, except the moon, of sufficient magnitude to obscure so completely the whole, or even so great a portion of the sun's disk as we often observe in a common eclipse; as the eclipse also invariably happens about the middle of that interval that elapses between the moon's disappearance in the morning, to the west of the sun, and her re-appearance a few days after in the evening to the east of the sun, and as the opaque body seemed to move over the sun from west to east, the direction of the moon's proper motion, it can hardly be doubted, from all these circumstances, that the opaque body which thus darkens the sun is the moon.

Eclipses of the moon.—But the moon is herself subject to eclipses, both total and partial, in which her darkened portion sometimes disappears entirely, and sometimes is still faintly visible, though very much obscured. But here it is the eastern portion of her disk which first disappears, and is the first to re-appear, just as if, in her course from west to east, and deriving nearly the whole of her light from the sun, she had entered and passed through the shadow of a round opaque body. Now we are quite certain that the earth is opaque, and almost equally so that it is round; at the time of an eclipse, also, the moon is always at the full, and directly opposite to the sun, the earth being so exactly situated between them as to cast a shadow behind itself, which might fall upon the moon. As we can disoover no other body in the heavens, uniting so many requisites for producing an eclipse, it amounts almost to certainty, that this is the true cause of the appearance, and it confirms the above explanation of the solar eclipses.

As the moon disappears when the light of the sun is withdrawn by the earth's interposition, and gradually re-appears as she emerges from the earth's shadow, exactly as it happens to all dark objects when deprived of the light necessary to perceive them, as the objects in a room disappear upon withdrawing the candle, and re-appear when we re-admit it, we conclude that the moon derives her light from the sun, and that it is only by his shining upon her that we ever see her in the sky, in the same manner as we often observe distant spots of ground and the objects within them become brighter and more visible than the surrounding ones, as the sun shines upon them through openings in the clouds.

Phenomena of the sun and moon.

Explanation of her phases.—The moon then seems to resemble the earth in the properties of opaqueness and want of internal light. If we extend the analogy to the property of roundness in every direction, which is certainly probable, we shall have a very elegant explanation of the monthly variations in the extent of her light.

For as it is clear that no more than the half of a globe can be enlightened by a candle at a time, and also that no more than its half can be seen by us at a time, so it will happen with the globe of the moon: no more than one-half of her surface, or a hemisphere, can be enlightened by the sun at a time, while no more than that half of her which is next us can be seen by us at a time. The moon, then, will always have one hemisphere wholly dark, and the other wholly enlightened. Now, if it should happen, that the hemisphere which is next to us should be at the same time the one which is wholly darkened, it is plain that we could no more perceive the moon than if she had no existence; and, on the other hand, if that side of the moon which is turned towards the sun should be, at the same time, wholly enlightened, it is equally clear that we should see her under the form of a complete circle. But the one of these cases would obviously happen at the change of the moon, when she is between us and the sun, as at *h*, Pl. 21. Fig. 15. (being then most commonly either north or south of the sun, above or below the paper in the figure,) for then her enlightened half, A B C, would be turned from us, and the dark half towards us; the other case would happen at full moon, at *d*, (she being then, as before, a little north or south of the sun,) when the enlightened half, A B C, is towards us, and the dark half from us; the line A C, which separates the light from the dark hemisphere, coinciding in both cases with the line which separates the half that is next us from the half that is opposite us.

Now, these appearances which we have thus anticipated from theory, are exactly what we observe in following her phases. At the change of the moon she is always invisible, and at the full moon she seems a whole circle of light, except in the case of eclipses, when she is seen, on the one hand, like a dark spot upon the sun, and, on the other, is concealed by the shadow of the earth. It is, therefore, more and more probable that the moon is a spherical body, and that she appears and disappears successively, in consequence of being brought, by her monthly revolution round the earth, successively between and opposite to the sun, the source of her light.

Moon much nearer us than the sun.—This conclusion would be farther verified, could we compare her observed semicircular appearances in her quarters with the theoretical deductions. But her appearances at her quarters must depend upon the linear distance of the sun. Let S, Fig. 15. be the sun, and A a B C c D, the moon in her first quarter; then A a B C will be the enlightened half, and D A a B

Phenomena of the sun and moon.

the half next the earth; in this case more than the half of the moon will evidently be visible, nearly in proportion as the enlightened portion, A a B, of the half next the earth exceeds the dark portion, AD. If our theory be correct, then the sun cannot be in the position S, for we should then see more than the half-moon at quarters, which we do not. Neither can he be at s, or *s*, for though we should then see less extent of light than formerly, we should still see more than the half-moon, in proportion as a B exceeds a D. It is evident, therefore, that the figure which our theory would ascribe to the moon at the quarters, approaches to a half circle, as the sun is supposed to be farther and farther from the earth,—as his distance is supposed to bear a less and less proportion to that of the moon. Now, as the moon's figure at her quarters is actually observed so near as not to be distinguished from a half circle, we may conclude from this simple observation that the sun's distance from the earth is so great as to bear a very small proportion, indeed, to that of the moon.

It is to the sun's immense distance, then, which is no way inconsistent with any of our observations, rather than to any error in a hypothesis which explains all the phenomena by a law of so much simplicity and elegance, that we are to ascribe the moon's semicircular appearance at her quarters. And since she thus disappears entirely at the change, and gradually increases till she arrives at the full, by her enlightened hemisphere coming more and more into our view, it is easy to conceive that she must go through all the intermediate gradations, from the fine thread of light to the crescent, from the crescent to the half moon, and from the half to the whole circle.

And much smaller.—The moon being so much nearer us than the sun, and still only appearing of the same magnitude, must necessarily be smaller in the same proportion, as the object C D, Fig. 13. in order to have the same apparent magnitude when transported to E, must be really enlarged to the magnitude *c d.*

We may conclude, then, upon the whole, that the moon, like the earth, is a round opaque mass of matter, without internal light, insulated in space, much less distant, and therefore much smaller than the sun, and revolving round the earth from west to east, from the sun to the sun again, in $29\frac{1}{2}$ days, while she, at the same time, participates in the general motion of all the stars from east to west, rising and setting every day.

Sect. III. *Motions of the Sun.*

Annual motion.—To follow the proper motions of the sun, let a spectator, at any time of the year, remark a brilliant star, or group of stars, setting a little after the sun. In a few nights after, if he look again to the same quarter of the sky, he will no more perceive the same stars, but a quite different group, setting after the sun. On looking, however, in a few days more towards the east, the stars which he had missed in the west will now be observed near the horizon a little before sun-rise, and therefore eastward of the sun. Since the sun, then, is observed first on the west and then on the east of the same stars, he seems evidently, like the moon, to be making a progress among the stars towards the east, which, being more gradual, it only requires a little longer observation to perceive.

Phenomena of the sun and moon.

Each succeeding week the sun will be observed to rise later and later after the group of stars; new stars will successively disappear in the splendour of his rays, and re-appear when it is withdrawn by his eastward advance, and in the period of about $365\frac{1}{4}$ days, which forms *the year*, the same star as before will be observed to set a little after him in the evening; he is then in the same position as before relatively to the stars, after having made the complete circuit of the heavens. The sun, then, like the moon, seems also to revolve round the earth, though in a much longer period, and this is called his *annual* motion.

Equator.—But there is one circumstance regarding this motion, that must be particularly remarked, on account of the important consequences that arise from it. The proper, or annual motion of the sun, is not directly contrary to the diurnal motion; it is not due east, and would not be accurately represented by supposing the sun attached to a sphere which should revolve upon the same axis with the celestial sphere, but in a contrary direction, and only once in a year. For example, let P Q p E, Fig. 1. be the celestial sphere, revolving round the earth A, a mere point in relation to the sphere, on the axis P p, and in the direction E A Q, each star, a, 1, E, t, describing the circles a b c, 1 b 2, &c. which must be conceived to rise in relief above the paper towards the centres, b b, &c.; that circle, E A Q, which is equally distant from both the poles, (E P being equal to E p, and Q P to Q p,) is called the *equator*. Suppose, now, the sun to be at E, describing the equator, E A Q, by the effect of the diurnal motion, it is evident that, were his annual motion directly contrary to this, he would be always in the equator, moving in the direction Q A E, from Q all round to Q again, in a year; he would always therefore rise at the same point of the horizon, and ascend to the same height, H Q, in the sky, making the days always of the same length; nor would he ever advance any nearer to the north, or any farther from the south pole, at one season than at another, but would always remain equally distant from either.

The slightest observation, however, is sufficient to shew how far he really deviates from this imaginary course. For if, in the heat of summer, a spectator stand with his face to the south, he will then observe the sun rise behind him, ascend to a great elevation, and set behind him; while in the middle of winter he can observe, without turning himself, both his rising and setting, the height to which he ascends being also much less than formerly. From this period the sun is observed to rise and set farther and farther towards the north, and to mount higher and higher into the sky every day, until the middle of summer, when he returns in the same manner towards the south.

Tropics—Ecliptic.—That point of his course where the sun arrives in the middle of summer, when he is nearest the north pole, and just beginning to return to the south is called the *tropic of Cancer*, and that point where he arrives in the middle of winter, when he is nearest the south pole, is called the *tropic of Capricorn*. The one is at the same angular distance from the north that the other is from the south pole; so that the orbit of the sun—the annual circle of

Phenomena of the sun, moon, &c.

the heavens which he describes—and which is called the *Ecliptic*, crosses the equator, lying the one half towards the north, and the other towards the south pole, and the two circles have thus the appearance of two hoops, Fig. 17. crossing each other at a small obliquity. Thus, in Fig. 1. if E A Q be the equator, R A t will be the ecliptic, the one being inclined to the other by the angle Q A R, which is nearly one-fourth of a right angle. When the sun is in the tropic of Cancer at the point R, he then describes, by the effect of the diurnal motion, the circle R T, rises at the point d, ascends to the elevation H R, and makes the days longer than the nights, in proportion as the arc $d\,b$ R above the horizon exceeds the arc d T below it—while his arrival at the tropic of Capricorn, in the middle of winter, exactly reverses the situation of day and night—the arc $f\,r$ being now equal to d T, and $f\,t$ to d R, so that the day is now shorter than the night in the same proportion as in summer it was longer. The sun now rises at f, much farther towards the south H, and ascends only to H r; in returning towards the north, the day is continually lengthening, and the night shortening, till it again reach its maximum at R, while, at the intermediate point Q, when the sun describes the equator by the diurnal motion, the day is equal to the night, Q A being equal to E A. It is from this circumstance, therefore, of the sun taking a direction oblique to the equator, that arises all the variety of the seasons.

In every season the sun is in a different part of the ecliptic; and, to express these various positions, this circle is conceived to be divided into 12 equal parts, called *Signs*, of which the following are the names, the characters, and the months, about the 22d day of which the sun enters them:

Aries ♈	*Taurus* ♉	*Gemini* ♊	*Cancer* ♋
March	April	May	June
Leo ♌	*Virgo* ♍	*Libra* ♎	*Scorpio* ♏
July	August	October	September
Sagittarius ♐	*Capricornus* ♑	*Aquarius* ♒	*Pisces* ♓
November	December	January	February.

These names are taken from certain groups of stars lying on each side of the ecliptic, whose figures were thought to resemble those of the above animals. The space in which these figures are included, forms a zone or belt all round the sphere, and the ecliptic is in the middle of it. This zone is termed the *Zodiac*, and the signs *Signs of the zodiac*.

The proper motion of the moon is not directly contrary to the diurnal motion any more than that of the sun, though we supposed this to be the case in considering her phases, in order to simplify the appearances. In the middle of winter, when both the rising and setting of the sun can be seen without turning from the south, the moon, in disengaging herself from the sun, is observed to rise and set nearly at the same points, and ascend nearly to the same elevation in the sky. But being observed at the full, she is seen to rise and set behind the spectator, looking to the south, and to mount to a great elevation in the sky.

The planets.

The reverse of this happens in the middle of summer. The moon then rises with the sun, at the change, to a great elevation, and at the full seems to be in the opposite part of the ecliptic, rising and setting nearly as much towards the south as the sun rises and sets towards the north, and not ascending nearly to so great an elevation.

The moon then describes, in a month, nearly the same circle of the heavens which the sun describes in a year. That she does not, however, describe exactly the ecliptic is evident; for, let S, Pl. 22. Fig. 1. be the sun in the ecliptic S C A, M the moon, in her orbit M B, if we now suppose M B to be in the same direction with A S, that is, if M B neither rises above nor fall below the paper at any point, but is wholly coincident with it,—then M will come directly between the sun and earth E, and we should thus have a solar eclipse once every month, which does not happen. The moon's orbit then is a little inclined to the ecliptic.

Sun's motion only apparent.—The motion of the sun round the earth may be only apparent, and owing to a real motion of the latter round the former; for the appearances relatively to each other would be the same in either case. If we suppose, however, the earth to move round the sun, it must carry the moon along with it; for, let the earth E, Pl. 22. Fig. 2. in moving round the sun S, come into the position e,—if the moon M, in revolving round the earth, were not also carried with the earth round the sun, she would be occasionally observed beyond the sun, which never happens. Either, then, the sun and moon move round the earth, in concentric circles, as at Fig. 1.; or, the earth, E, Fig. 2. moves round the sun S, and carries along with it the moon M, which at the same time revolves round the earth once every month. The latter supposition seems certainly the least simple of the two; but it is only by comparing it with the rest of the system that we can decide which to adopt.

Chap. III. Of the Planets.

Five bodies, besides the sun and moon, are observed to have motions peculiar to themselves, while they all participate in the diurnal motion, rising and setting every day. They are called *Planets*, or wandering stars, those only in which we observe no proper motions being called *fixed* stars, from which also the planets are distinguished by having less (hardly any indeed) of what is called the *twinkling* of the stars. They have been known from the remotest ages; and the following are their names and the characters by which they are distinguished:

Mercury,	Venus,	Mars,	Jupiter,	Saturn.
☿	♀	♂	♃	♄

Distances.—As these bodies, like the sun and moon, seem to move among the stars without ever being hid from us by them, or impeded in their progress, they are also probably nearer us than the stars.

Venus.—Every one must have observed a beautiful star in the west, which sometimes shines with uncommon lustre in the evening, a little after sunset, and is called the *evening star*. This is Venus. By observing her for successive nights, we find that her distance from the sun remains not always the same. After her first appearance, she is observed on the succeeding evenings to set later and later after the sun, and thus seems gradually receding from him towards the east, till she arrives at an angular distance, equal to about a quarter of the hemisphere. This happens about two months from her first appearance. She then begins to return towards the sun, to set each night sooner and sooner after him, and at last disappears in the splendour of his light.

But, in a few days, a brilliant star makes its appearance in the east, a little before sun-rise, called the *morning star*. It is observed the succeeding mornings sooner and sooner before sun-rise, and seems therefore to be receding from the sun towards the west. This digression continues for a period of about two months, when the star has attained an angular distance from the sun equal to about one-fourth of the hemisphere; it then seems to return towards the sun, rises later and later every day, at last overtakes the sun, rises along with him, and we no more perceive it. It is a few days after that we discover again in the west, the evening star disengaging itself from the sun's rays, and again gradually advancing towards the east; and the striking resemblance between the two objects which thus succeed each other in the sky, their never having been observed together, their proceeding in the same periods to the same angular distances from the sun, and the observation of all these phenomena for ages together, leaves no room to doubt that it is the planet Venus which thus becomes alternately the morning and evening star, as she seems to oscillate on each side of the sun.

Mercury.—Mercury exhibits the very same appearance as Venus, on a smaller scale. Its oscillations on each side of the sun are confined within less than one-sixth of the hemisphere; and it is on this account less disengaged from the sun's rays and seldomer observed. It seems also smaller, but sometimes very brilliant.

Real motions.—These oscillations, however, may be only apparent. For as it is certain, that whatever progressive motion, relatively to the earth, these bodies may have, we can no more perceive it, on account of their distance, than if it had no existence. So if we ascribe to them a motion of revolution round the sun, the same oscillatory appearances would still be observed. Suppose, for example, Mercury M, Pl. 22. Fig. 3. and Venus V, to move in the circles M m, V v, round the sun S, and to be viewed by a spectator on the earth at so great a distance that they may successively assume the positions 1, 2, 3, 4, without appearing in the least degree to have receded or approached him, it is evident that they would seem to him to move in the lines M m, V v, from V to v, and from v back again to V; sometimes from west to east, or *direct;* sometimes from east to west, or *retrograde;* and sometimes, near the points V, v, to remain quite *stationary*; while, to a person at the sun, they would seem, like our moon, to move always in the same direction; just as a horseman, running in a circle, when viewed from a great distance, seems to move first in one direction and then in the opposite; while, to a person within the circle, he moves always one way.

Inferior and superior planets.—Mercury and Venus are called *inferior planets*, because they keep within a certain distance from the sun; the others recede to every possible angular distance, and are called *superior*. They are sometimes observed, like the moon, in opposition to the sun, beyond the earth, and sometimes at every intermediate angular distance, till they disappear in his rays. They keep, however, always within certain limits of the north and south, and never advance much farther than the sun towards the north or south pole, so that their paths, like the moon's, are slightly inclined to the ecliptic. They seem also to move with great irregularity, but they resume the same series of changes after certain periods. Sometimes their motion seems direct, sometimes retrograde, and sometimes they appear to remain for considerable periods in the very same position among the stars. As it is certain, however, that these bodies, though thus apparently stationary, may in reality be moving with the same velocity as before, while the mere circumstance of their motions being now progressive relatively to the earth, might conceal it entirely from our view; so all their irregularities, like those of Mercury and Venus, might vanish to a spectator on the sun.

Chap. IV. Solar System.

There is, accordingly, a hypothesis, which confers the greatest simplicity on these complicated appearances. It supposes the superior, like the inferior planets, to circulate round the sun at greater distances, as they are longer of completing their revolutions, according to the order above enumerated. It supposes also the sun and planets to form a distinct group in the system of the world, separated all round from the fixed stars by a distance almost inconceivable. And by converting the apparent motion of the sun round the earth into a real motion of the latter, along with the moon, round the former, it adds the earth itself to the list of the planets, while, by ascribing to it at the same time a daily rotation on its axis, it renders illusory the diurnal motion of the stars.

We have here a system, at all events, of order and consistency; a set of bodies of various magnitudes moving at various distances, and in various periods, round a great centre of heat and light; a system, also, according to which the apparent confusion of the planetary motions arises entirely from our viewing them from a disadvantageous position.

Our position upon the earth would have this effect in two ways; first, being out of the centre round which the planets revolve, they would be nearer us in one part of their course than in another; and would, on this account, appear to move quicker at one time than at another, though their motions round the sun were perfectly uniform. Thus, let E, Fig. 4. be the earth, which we shall suppose at rest, and P one of the superior planets moving round the sun S, in the orbit P A B C. Advancing from P, in the direction P A B C, the planet will evidently recede

Solar system.

from the earth till it arrives at B, and will then approach till it returns to its first position. Suppose it now to move *uniformly* round the sun, that is to say, to describe equal portions of its orbit P 1, 1 2, 2 A, A 3, &c. in equal times in each month for example, it is clear, that p a b c, representing the celestial sphere, p, 1, 2, a, &c. will be its positions among the stars, as seen from the earth,—the points of the celestial sphere in which it is observed at the end of each month. Though the planet then really describes equal portions of its orbit every month, yet to a spectator on the earth, out of the centre of the planetary motions, it will seem to describe among the stars smaller and smaller spaces, P 1, 1 2, 2 A, A 3, &c. as it approaches B; to him, therefore, it will seem to move slower and slower as it advances to B, and quicker and quicker as it advances from B to P.

Secondly, The *motion* of the earth would have a sensible effect upon that of the planets. Every one must have remarked how much his own motion affects the apparent motion of the surrounding objects. A traveller in a coach observes the trees and houses that border the road pass by him with great rapidity, while the more distant objects remain longer in view, and seem nearly at rest. In this case, our own motion makes us ascribe motion to bodies at rest. It has often, however, the contrary effect. A spectator on shore remarks a rapid motion in a vessel at sea, while the passengers in the cabin, if they are sailing in smooth water, imagine themselves, as well as the objects around them, in complete repose.

The motion of an object, indeed, is nothing else than the continued change of its position, that is, of its linear or angular distance—its remoteness or its direction relatively to the observer; its direction being estimated from that of one or more known objects which we suppose at rest, as that of a spire, a signal post, or the north or south. Now, we always remark a change in the position of the surrounding objects, as well when we change our own position as when they change theirs. Our distance from a vessel at sea is continually diminishing, whether we approach it or it approaches us. The vessel seems also to advance towards the north or south, either when we stand upon the shore and observe it actually sailing in these directions, or when the vessel is at anchor, and we ourselves are travelling towards the south or north. The apparent motion of an object, therefore, necessarily varies with the motion of the observer. So it will happen, according to the above theory, with the motions of the planets. Their real motions, relatively to the fixed stars, which an observer at the sun would only remark, will, to a spectator on the earth, be combined with his own motion round the sun; and these two being sometimes in one, and sometimes in opposite directions, their joint effect will be extremely irregular. Thus, let E, Fig. 5. be the earth, and P one of the superior planets, setting out together from the points E and P, and moving uniformly round the sun, the earth in one, and the planet, suppose, in eight years; then will P, 1, 2, 3, &c. and E, 1, 2, 3, &c. be a series of their corresponding positions, the planet having only advanced to 1, when the earth has gone over one-fourth of its orbit; the former also being only at 4, when the latter has completed its circuit, and so on.

2

Fixed stars.

Let A B C D represent the sphere of the fixed stars, to which we refer the position of the planets, and let A B C D be the direction from west to east in which they move when their motion is said to be direct; then will p, 1, 2, 3, 4, &c. be the series of the planet's position among the stars, as seen from the earth, corresponding to its actual positions, P 1, 2, 3, &c. in its orbit, as seen from the sun. When the earth is moving from E to 1, the planet will seem to be moving from p to 1, contrary to the direction A B C D. Though both the earth and planet, therefore, are really moving direct, the latter, to an observer on the former, will seem to be retrograding. While the earth moves over the next quarter revolution, from 1 to 2, the planet will seem to move from 1 to 2; its motion, therefore, will now be direct; while the earth advances to 3, E, the planet will seem to advance to 3, 4; but when the former comes again to 1, the latter will seem to have returned to 5. In the next revolution of the earth, the planet will seem to advance successively to 6, 7, 8, 9; but when the former arrives at 1, the latter will seem to have returned to 10. The same irregularities continue through the whole of the planet's course; and it is easy to conceive, that, during each transition of its motion from direct to retrograde, and from retrograde to direct, there must necessarily be an interval of apparent repose. These effects are considerably modified by the amazing distance which the theory ascribes to fixed stars; but it will easily be perceived, in general, from what has been said, how the planetary irregularities might be accounted for in this way.

The above system has been called the *Solar* or *Planetary*, and sometimes the *Copernican* system, from Copernicus, a Prussian, by whom it was revived and illustrated, after having been neglected from the age of Pythagoras, who is said to have first proposed it. It could hardly have been suggested by any observations that could be made without the aid of instruments; but we have given the above outline of it, that, in treating of the discoveries of more precise observations, the reader may be the better enabled to discern how admirably they all bear upon this grand point.

Chap. I. Of the Fixed Stars.

Number of the stars.—Viewed in a clear winter night, when there is no moon-light, the stars appear quite innumerable; but, upon a closer inspection, and by only examining one group at a time, a spectator will be surprised how few are visible in the whole hemisphere. In this manner, it is found, that a good eye can scarcely ever distinguish more than a thousand.

Constellations.—To distinguish the individuals of such a number of objects, the usual mode has been adopted of dividing them into classes, which were termed by the ancients *Constellations*, and each of which they designated by the name of some animal which the figure of the group was thought to resemble. The stars of each constellation are then distinguished by the letters of the Greek alphabet, according to their magnitudes, the largest being term-

Fixed stars.

ed α, the next β, and so on. In this manner, every star in the heavens has a particular name; and thus the astronomer, to whom they serve as so many fixed points, with whose positions he compares that of the planets, is at no loss to describe the particular star he may have in his eye.

Magnitudes.—The stars of each constellation, however, have in many cases particular names, besides that which they receive from the Greek alphabet. Thus, the largest in the constellation of the Lion is called *Regulus*, as well as α of the Lion; and the whole stars have also another arrangement, according to their *magnitudes*.

Those which seem the largest and brightest are called *stars of the first magnitude*. The smallest that can be seen with the naked eye are of the *sixth magnitude;* and the intermediate ones, according to their sizes, are of the *second*, *third*, &c. magnitudes.

Principal stars.—Let a spectator observe the heavens in a clear winter night of the month of December or January, and about ten o'clock he will observe a very remarkable group of brilliant stars towards the south, and considerably elevated above the horizon. This is, the constellation *Orion*. Of four bright stars, arranged in an irregular square, the two highest form his *arms*, and the two lowest his *legs*. In the centre of this quadrilateral are placed in an oblique line, and quite near each other, three other bright stars forming the *belt* of Orion, and beneath these are three others of inferior lustre, which are thought to design his faulchion. The three stars of the belt, which are sometimes also termed the *three kings*, point on one side to *Sirius*, or the *Dog-star*, and on the other to the *Pleiades*. Sirius is that remarkable star distinguishable from any other by its scintillation and lustre; it is to be seen on the south-east side of Orion.

The Pleiades, or the Seven Stars, lie on the north-west of Orion; they are very easily known by being so closely massed together. Besides, they are almost in a direct line from Sirius, through Orion's belt. They are on the back of another constellation called *Taurus*, or the *Bull*.

That very large star on a right line, half way betwixt the Pleiades and the star that forms the western shoulder of Orion, is called the *Bull's eye*, or, *Aldebaran*.

That large star which, it may be perceived, forms a triangle of equal sides with Sirius and Orion's belt, is called *Procyon*, or the *Lesser Dog*. It lies to the north of Sirius, and to the east of Orion.

Imagine a straight line extending towards the north from Procyon, or the Lesser Dog, and the first star it meets with is *Castor*, or one of the constellation called *Twins*, very near which is another bright star called *Pollux*, the second of the Twins. This lies south-east with regard to Castor.

Those four stars that lie in a right line, at equal distances, and about half way betwixt the east shoulder of Orion and the Twins, are the *four feet* of the Twins.

A line drawn from the bright star that forms the west foot of Orion, through the star in his western shoulder, leads to the next star, called the *southern horn of the Bull*. This star, and the west foot of Orion, are equally distant from his west shoulder.

The northern horn of the Bull is brighter than the southern; it lies on a straight line with the east shoulder of Orion and the southern horn of the Bull.

The ecliptic, or the annual course which the sun seems to take in the heavens, passes betwixt the two horns of the Bull.

A line prolonged from the west foot of Orion, through Procyon, or the Lesser Dog, leads to that very bright star called *Regulus*, or the *Lion's heart*, which lies east by north-east from Procyon, and at some distance from it.

A line drawn from the star in the middle of the Twins, through Regulus, will then pass beneath a square of bright stars near Regulus, which form the constellation called the *Lion*. The first bright star, lying east by north-east from Regulus, and almost as large as itself, is called the *Lion's tail*.

A line drawn from a bright star that lies half-way betwixt the feet of the Twins and their heads, towards a bright star that lies east, will pass through the *Crab*, which lies exactly half way betwixt the Twins and the Lion, remarkable by one bright star and a cloudy clump of small stars adjoining to it. This constellation is difficult to be remarked.

Suppose a line drawn through the Twins, north-west by north, it will touch a bright star in the helmet of the constellation called *Auriga*, which is at a considerable distance.

A very conspicuous star lies south-west by south from this one. This beautiful star is called the *Goat*; and due east, opposite to it, lies another, which, with three or four more near them, situate to the south, forms the whole constellation called *Auriga*.

A line drawn from Procyon, by Aldebaran, westward, leads to the constellation called *Aries*, or the *Ram*. This is reckoned the first constellation in the heavenly order, since the mass of stars that form its head lie nearest that point where the sun equally divides the year, making the nights equal to the days. The first star in the Ram's horn, which is the star astronomers reckon from, lies thirty-six degrees more to the west than Aldebaran.

Imagine a line drawn from the Seven Stars, or the Pleiades, north north-west, and the first star it meets is the first star in the *breast of Perseus*; the star to the north-west of this is his right shoulder, the star to the west is the left, and the very brilliant star, south by south-west of the breast of Perseus, is the first star in the constellation called *Medusa's head;* next to which there are three others very near, that form the whole head, something in the form of a square.

The very bright and beautiful star, lying east by north-east from the Lion's tail, is *Arcturus*, the largest in the constellation called *Bootes*, situate between his legs.

The mass of stars west by north-west of Arcturus, between it and the Lion's tail, is called *Berenice's lock*.

A line drawn from Arcturus, north by north-west, falls in with the last star of the tail of the capital constellation called the *Great Bear*. This last is formed

Fixed stars.

by seven stars, in the form of a plough. It is the most conspicuous constellation in the heavens, and, therefore, may serve to point out others. Of this constellation the four stars that lie towards the north form an irregular square, of which the two stars that are the most northern, point northward to a bright star, not very distant, which is called the *Pole-star*, as it lies only about two degrees from the pole of the world.

The *Swan* is a very remarkable constellation, in the form of a great cross. A line drawn from the Twins, through the Pole-star, meets the Swan on the north side, at nearly the same distance.

A line drawn from the northern side of the square of the Great Bear, through the pole, passes through the middle of the constellation of *Pegasus*. This, too, is a square formed by four bright stars, the most northern of which forms the head of *Andromeda*. A line carried from the Pleiades to the Ram, falls upon *Algenib*, the beautiful star in the wing of Pegasus. The most northern stars of Pegasus are called *Scheat* and *Markab*; Scheat lies to the north, and Markab to the south.

Cassiopeia is a constellation directly opposite to the Great Bear, through the Pole-star, in such a manner that the line that passes through the middle of the Great Bear, by the Polar-star, passes also through Cassiopeia on the other side of the pole. This constellation is formed of six or seven stars, in the shape of a chair turned upside down.

Cepheus is that constellation contained betwixt the Polar-star, Cassiopeia, and the Swan. A line drawn from the Pole-star to the Swan's tail, passes through the two first great stars in the constellation of Cepheus.

The *Lesser Bear* has almost the same shape as the greater, and is parallel to it, but the situation is inverted. The Polar-star is the last in its tail. The two largest stars in this constellation are in a line drawn through the centre of the square of the Great Bear, perpendicular to both its greater sides.

The *Dragon's tail* lies betwixt the Polar-star and the square of the Great Bear. The four stars in its head lie south by south-east with regard to the Lesser Bear, and almost form an exact square.

Such are the positions of the most conspicuous stars which appear to us in a winter night. The others may be known either by means of a *celestial globe*, which is an exact image of the great sphere of the heavens, or by *celestial maps*, or *catalogues of the stars*.

PART II. ASTRONOMY IN ITS IMPROVED STATE.

The great object of astronomy is to discover the nature of the power by which the heavenly bodies are kept continually in motion. Like every other species of knowledge, this can only be attained by studying the effects of that power; namely, the motions themselves, and carefully comparing them one with another.

In Part I. we have considered the nature of these motions as far as can be collected almost by mere inspection; and though, even in this manner, our notions have become considerably more correct than at first,—though we have thus found that the earth, instead of being an immense plain, extending to the heavens, is a round mass of matter, insulated in space, and separated from the stars by a distance to which even its own great magnitude bears no sort of proportion—though we have found that the sun, the moon, and the planets, the two former at different distances from the earth, and all of them probably nearer us than the stars—have motions peculiar to themselves, while at the same time they all participate in the diurnal motion of the stars—we are still left completely in the dark as to any great principle to connect these complicated phenomena together.

Astronomy, therefore, could hardly ever have advanced beyond its infancy, with this rude instrument of observation. To obtain a more perfect knowledge of the phenomena, and of their causes, it was necessary to compare them together in a much more accurate manner, and to substitute for inspection the more refined process of *measurement*. It is accordingly by this happy application of *instruments* to aid the imperfection of our senses, that astronomy has been brought to its present state of improvement. To make the subject, however, in the least degree intelligible in this view, it is absolutely necessary that we explain, and we shall do so as shortly and as distinctly as possible, the general principles upon which these measurements are affected.

Chap. I. Measurement of Quantities in Astronomy.

Sect. I. *Quantities which occur in Astronomy.*

Force.—The forces, as we have already observed, which animate the heavenly bodies are the ultimate objects of the astronomers researches. "The nature," says La Place, "of that singular modification, by virtue of which a body is transported from one place to another, is and will always be to us unknown. It has been termed *Force*; but its effects, and the law of its action, is all that we can possibly determine."

Space and Time.—In putting a body into motion, force is distinguished by two distinct effects—one by which it makes the body describe *space*, the other by which it makes it describe *time*. A body in motion is not only transported through successive portions of space, but also through successive portions of time. Thus, when a stone is thrown into the air, not only does it continually rise higher and higher, and then descend in the same manner, but in each part of its course, from its projection to its greatest elevation, and thence to its fall; it marks out and carries as inseparably along with it to the mind the idea of successive intervals of time.

In estimating the intensities of forces acting with various effect upon the same moving body, these two quantities, space and time, are the only elements which enter into the calculation. A person, for example, is in the daily habit of observing a mail coach

Of quantities.

pass by his house, and being surprised one day at the uncommonly exhausted state of the horses, finds, upon inquiry, that they had started at the usual hour, but owing to an accident had been obliged to run a part of the preceding stage, that they had therefore run over a greater *space* than usual in the same time. Upon this his surprise immediately ceases, as the cause seems quite adequate to the effect. On remarking the same circumstance another day, he is again satisfied, on being informed, that the coach was later than usual in setting out; that the horses, therefore, had run their course in much shorter *time* than usual. The intensity of a force then depends neither entirely upon the space over which, nor upon the time during which the body moves, but upon the mutual relation of those two quantities.

Velocity.—This relation is denoted by the term velocity; it is the space which a body describes in a given time; the number of feet, for example, which it passes over in a second, in a minute, or in an hour. Thus, a person on horseback, is said to go quicker,—to have a greater velocity than a person on foot, because he moves over a greater space in the same time. When no time is mentioned, a second is always understood; and in this view, the velocity of a body is nothing more than the space which it describes in a second.

The problem of the forces which animate the heavenly bodies being thus reduced to the discovery of their velocities, the question of their successive positions, both in point of space and in point of time, by which their velocities are determined, becomes in the first instance the great object of inquiry. These are the quantities which the astronomer is almost constantly occupied in observing; the whole efforts of the artist being in the mean time directed to the invention and improvement of the instruments by which they can be most precisely measured; and and the whole efforts of the mathematician to the discovery of methods of calculation that may enable him to determine the conclusions to which the observed velocities would lead,—the nature of the forces which they would indicate.

Sect. II. *Measurement of Space.*

Space, or distance, as we have already seen, is of two kinds, linear and angular. Linear distance is measured by selecting any portion of it, as a standard with which every other may be compared. But as there is no body in nature which is always of the same extent, this selection is quite arbitrary. In this country the standard measure of distance is the foot; by its continued repetitions, we express larger distances, as miles—and smaller ones by its continued subdivision into inches, tenths, &c. When the objects whose distance is required are accessible, it is measured by the actual repetitions of the standard, but it is only by combining their angular with their linear distance, that we can discover that of inaccessible objects; and this being the case with all the heavenly bodies, it is hence in the measurement of angular distance that the astronomer is principally concerned.

Measurement of angles.—The whole circuit is here, as we have already seen, a fixed standard of comparison. Its parts may be measured by any line, A E, Plate 22. Fig. 6. drawn across the lines which contain the angles. Being cut by the diverging lines a B, a C, a D, its sections, A B, A C, A D, would evidently indicate the comparative magnitude of the angles A a B, A a C, A a D, &c. as well as that of the angles B a C, C a D, &c. by the parts B C, C D. But as it is only (p. 482.) when an object revolves round a point, that it exhibits all the degrees of angular extent, in the same manner it is only some line which re-enters into itself, by whose division into parts we can compare one angle with another. For unless the direction of A E were changed, it would evidently fail in the case of the right angle A a F, as the line A F, being parallel to A E, would never cut it. Besides this, the sections A B, B C, of the line A E, corresponding to the *equal* angles A a B, B a C, &c. have the inconvenience of being *unequal.*

Now, of all re-entering lines, the circumference of the circle is the only one which, being cut by lines diverging from the centre, has the property of making equal angles correspond to its equal sections, and as it thus affords peculiar facilities for minute subdivision is has become, in fine instruments, the universal scale for the measurement of angles. Its division into parts is quite arbitrary, though its quarter, the measure of the right angle (p. 482.) seems naturally the first subdivision. There are only two systems of division, the *sexagesimal* and the *decimal* divisions, that have ever been much adopted; and of these the latter, having been only of late introduced by the French astronomers, is much less extensively used than the former, though recommended by its coincidence with the decimal scale of our arithmetic.

The radius a A (Fig. 7.) of a circle goes exactly six times round the circumference, dividing it in this manner into six equal parts, A B, B C, &c. and hence the sexageximal division has probably arisen. In this division each sixth part, A B, B C, is subdivided into sixty smaller portions, called *degrees*, of which the whole circumference, therefore, contains six times sixty, or 360; each degree is again divided into sixty equal parts called *minutes*, and each minute again into sixty *seconds*. These subdivisions are marked by the following characters: Degrees°, minutes′, seconds″: Thus 10° 15′ 20″, denote 10 degrees, 15 minutes, and 20 seconds; each second is less than the millionth part of the circumference; but to this extreme degree of minuteness has the refinement of modern art succeeded in measuring angular extent.

The principle of all angular instruments is the same. In their rudest state, they consist each of a circle, or portion of a circle, A B C, Fig. 8. the circumference of which is divided into degrees, minutes, &c. It has attached to it a piece A C, termed its *index*, moveable round its centre O, and extending to the circumference, which being directed first to one object P, and then to another Q, the circle itself remaining all the while fixed, indicates by the interval A B, between the two positions upon the circumference, to which it successively arrives, the angular distance of the two objects—the number of degrees, minutes, &c. contained in the angle P O Q.

The larger the circle A B C is, the greater is the accuracy of the observations. The ancient astronomers accordingly employed instruments of great size;

Of quantities

to make the index also point more directly upon the object, they used two *sights*, or two upright pieces. A B, Fig. 9, fixed at the extremities of the index, and pierced each with a small hole or slit, through which the objects were observed.

In modern times methods have been invented for subdividing the degrees without enlarging the circle. The admirable discovery also of the magnifying power of lenses, by its application to read off the divisions of our instruments, admits their being reduced to a still more commodious form; while it carries them, perhaps, to their utmost perfection, by substituting, for the rude observation of sights, the astonishing power of the *telescope*.

Sect. III. *Measurement of Time.*

Time is measured upon the same principle as space, namely, by the repetitions of a certain portion of it indicated by an event. In both cases the accuracy of the process depends evidently upon the dimensions of the unit remaining unvaried in all its repetitions. Heat and moisture are the only circumstances which have been found to affect the extent of bodies. The varying causes of the duration of events are much more numerous and less easily estimated. The measurement of time is, accordingly, a problem of the highest practical difficulty.

Year, day, month.—The heavenly bodies seem designed by nature for effecting this important purpose to mankind. Their motions furnish a succession of similar events, sufficiently obvious and minute for all the purposes of uncivilised life; and they have also been found to surpass in uniformity the utmost refinements of art. Those of the sun are the most striking and most remarkably distinguished by their connection with the labours of man and the operations of nature. The *year*, the period of his variations, has accordingly been universally adopted as the standard of comparison. His successive appearances above the horizon mark its subdivision into *days*, and the changes of the moon produce the intermediate period of the *month*.

Time-piece.—The purposes of an improved society, however, require divisions of time still more minute, and the whole process to be brought, if possible, into the commodious form of an *instrument*, whose indications can easily be observed. To the astronomer, also, it is of the utmost importance to obtain a measure of time, independent of the heavenly motions; for, being previously ignorant of the causes of the sun's motions, he is quite uncertain whether or not the successive events which they mark out are performed under the very same circumstances; whether, therefore, the days of the year, or the years of a century, are each of the same duration. Time, in short, being one of the elements whose knowledge is absolutely necessary for the discovery of these causes, it is equally indispensible that he possess a method of measuring it in some degree independent of the motions.

The principle of all time-pieces is the same. The great object in them all is to produce an invariable motion, so that the moving body may present, by the successive spaces which it describes, a constant succession of similar events; and thus indicate equal portions of time by the graduations of the space to which it successively arrives. This is precisely what is done in our clocks and watches, whose indices or hands are bodies of this description moving over the divisions of the dial-plate. A motion of this kind, by which a body describes equal spaces in equal times, is said to be *uniform*; and though any other motion would equally answer the purpose, if its variations were regulated by a constant law, uniform motion has the convenience of admitting the dial-plate to be divided into equal portions; revolving motion has also the obvious advantage of describing, and the circumference of the circle of measuring any extent of angular within the smallest compass of linear extent, and thus allowing the instruments the most commodious form that other things will permit. It is on this account that the uniform motion of a body upon the circumference of a circle has become universally the form of our time-pieces.

These instruments have only been brought to perfection by long-continued observation and experience. By comparing those of one construction with those of another, and all of them with the motions of the heavenly bodies, the circumstances which derange their uniformity have been gradually brought to light and corrected; and it has been found, that the more these deranging causes are obviated, their motions are only approaching nearer and nearer to those of the celestial sphere,—that their hands are only presenting a more and more perfect image of the revolutions of a star. It is by this standard of perfect uniformity, then, that the astronomer corrects the unavoidable inequalities of his clocks.

Sect. IV. *Positions in Space.*

Let us now consider the method of determining positions in space. The position of an object in space is that particular position of space which it occupies. Thus one it said to be in the middle of a room when he is equally distant from its opposite sides; and he is in the east or west end of it according as he approaches its eastern or western side.

It is plain that the position of an object, O, on the floor of the room A B C D, is not completely determined by its distance O G from either of its sides A B, or by O E, its distance from its end A D; for there are various other points, 1, 2, 3, &c. namely, all those in the line E O F, parallel to A B, which are at the same distance O G from A B; in the same manner as in a book there is a number of lines all in one page; and when we wish to refer to any particular sentence, as we must then tell the line as well as the page, so, in order to define the particular point O, we must also know its distance O E from A D, the end of the room. By knowing its distance from A B, the side, we only know the line E O F in some part of which it is situated; but by knowing besides its distance from A D, we get another line G O H, in which it is also somewhere to be found; as it is therefore both in E O F and in G O H, it must necessarily be the point O where these lines meet, and which is the only one that can be in both of them at once.

It is evident also, that any *other* two lines, $e\,O\,f$, $g\,O\,h$, passing through the point O, would, by their intersection, equally well determine its position; and even

Of quantities though they were not straight, but circular or curved in any other manner, as e f, g h, they would still only meet in a single point, and thus indicate its position. In general, then, when we know the *surface* (the floor of the room in this example) on which a body is situated, its position on that surface is completely determined by the intersection of *any two lines;* and it is therefore completely known (or *given*, as it is termed) when we know the positions of these lines.

When the position of objects is to be ascertained by actual observation, we must take those lines to determine it by their intersection whose position can be most easily measured. A spectator at A, for example, (Fig. 11.) wishes to know his distance from a house, H, beyond the lake L; he sets up a signal at B, measures with a chain the distance A B, suppose 1000 feet, termed *the base line*, and setting his angular instrument at A, measures with precision the angle B A H, and thus obtains the position of the line A H, upon which H is somewhere situated. Transporting his instrument to B, he measures in the same manner the angle A B H, and thus obtains the position of another line in which the house is also situated. These observations, therefore, afford the means of finding the point of intersection of the two lines, or the distance B H.

When there is a variety of objects, however, all whose positions are to be determined and enumerated, such as the stars, or the places upon the earth, or as 1, 2, 3, &c. Fig. 12, in order to bestow uniformity upon the expressions of these positions, it has been found convenient to reduce them all to a common standard; and when their positions are once determined by the intersection of those lines, to which the nature of the operation necessarily limits us, as they can then be easily expressed by that of any other lines chosen at pleasure, it has been universally agreed to fix upon some two lines, A B, C D, at right angles to each other, (and analogous to the sides of the room in our example,) and to express the positions of all the objects by their distances from them, 1 *a*, 1 a, &c. 2 a, 2 *a*, &c. to which a generic name, as *latitude, longitude*, &c. &c. is applied.

We have hitherto supposed the objects all situated upon a plane surface; but what has been said will also apply though the surface be spherical or any how curved, only the lines which in that case determine the positions of the points upon it will also have a corresponding curvature. But the heavenly bodies seem all at the surface of a sphere, and the surface of the earth is also spherical. Astronomers have accordingly agreed to use certain circles of these spheres, to whose position that of the points on their surfaces may be referred. These circles we shall now shortly describe.

Sect. V. *Positions in the Heavens.*

Circles of the sphere.—Every circle of a sphere may be conceived to be formed from what is termed the *section* of the sphere by a plane. Let any globe, for example, be cut in two by a plane, that is, by a body of any length and breadth, but as thin as can be imagined; and let the parts be re-united; the mark or curve which now appears upon the surface of the globe, all along the joining, is a circle, and is called the section of the sphere by that plane, and its position is indicated by that of the plane, which is termed *the plane of the circle.* When the sphere is cleft through the middle into two hemispheres, the plane then passing through the centre of the sphere, the circle, which is formed on the surface by this section is termed a *great* circle of the sphere. In every other case, that is, when the plane of a circle does not pass through the centre, it is termed a *small* circle. Of quantities

These circles, which arise from the actual section of a spherical body, by another flat body nearly deprived of its thickness, must be extended in idea to the sphere of the heavens, in order to have a correct notion of the circles which have been imagined for the purpose of determining positions upon its surface. But it must never be forgotten, that as that sphere has really no existence, neither have these curves, of which astronomers make so frequent mention. They are merely the circles that *would be* formed were the sphere a material substance, and were it intersected by actual planes, as we conceive it to be by imaginary ones.

Zenith.—The point of the heavens most easily recognised is that directly over our heads, or the *zenith.* It is sometimes difficult to recognise the north and the south, but the zenith is obvious to every one, and in every place. It is indicated with more precision by the direction of *a plumb-line*, and is the point in which the latter would meet the celestial sphere, being sufficiently prolonged above.

Vertical.—The line which joins the zenith and the observer, is termed *a vertical.*

Nadir.—That point under our feet in which it would meet the sphere by its prolongation below, is called the *nadir.*

Plane of the horizon.—If a plane be conceived to pass through the eye of the spectator, perpendicular to the vertical, this is called the *plane of the horizon*, and the circle which it forms on the sphere, by its prolongation on all sides,—the section of the sphere by this plane, is termed the *horizon.* It is the circle which separates to a spectator his visible from his invisible portion of the heavens,—the boundary of our prospect, as we have hitherto merely considered it. It is one of those circles to which the positions of the heavenly bodies are referred. But if it be merely a conception, it is not easy perhaps to see how it can serve as a point of reference. This will be understood, if we shew how its position can always be determined; it is always indicated by looking along the surface of the ocean, or any plane surface, as a board or a table, set perpendicular to the plumb-line. Angular instruments are accordingly fitted with a plumb-line, or, which answers the same purpose, a *spirit level*, by means of which the line of the telescope can be set with great precision in the plane of the horizon, and the angular deviation of the stars from this plane measured with equal nicety, the instrument being so constructed as to move from the right to the left, or the contrary, all round. The horizon, in this view, is nothing else than the imaginary union of that series of points which we observe in the telescope, when it moves in the plane of the horizon,—when it moves

Of quantities round with the bubble of the *spirit level*, always in the middle of the glass, or the line of the telescope, always 90° from that of the plummet.

Verticals.—Conceive now a series of planes, Z A B N B′ A′, Z a b N a′, Z *a b* N *a′*, &c. Fig. 13. all passing through the vertical of a place; or conceive a single plane to assume those various positions by revolving upon the vertical as an axis: these are called *vertical planes*; being prolonged on all sides towards the heavens, they cut the sphere in the circles Z H N O, Z h N, Z *h* N, &c. Fig. 14. which are termed *vertical circles*, or simply *verticals*; they are those circles which the eye traces in the heavens, by looking along a plane board set up in the direction of the plummet. The telescopes of angular instruments are made to move in a vertical by means of the plummet, or spirit-level, while they can be made to describe any vertical whatever by means of the horizontal movement above mentioned. All the vertical planes, along with their line of common section, are perpendicular to the plane of the horizon, and the great circles themselves are also perpendicular to the horizon; they form with it what are called *spherical angles*, Z H h, z h *h*, &c. and each of them is 90°, being always equal to the angles of their planes.

Altitude.—The position of a star, S, will evidently be determined when we know the vertical, Z *h* N, in which it is, and its distance from the horizon, S *h*,—the arc of the vertical intercepted between it and the horizon, H O; for there can be only one point of the same vertical at the same distance above the horizon. The distance is called the *altitude*, or elevation of the star. It is the angle, S E H, which the line joining the star and the centre of the earth, E, or the observer, z, makes with the plane of the horizon, (the line, E z, being considered as of no magnitude relatively to the distance of the star,) and is measured by the degrees, minutes, &c. in the arc of the vertical, S *h*, between the star and the horizon. It is actually observed by making the index of the vertical circle of the instrument point to *Zero*, or 0° 0′ 0″, when the line of the telescope is in the plane of the horizon, and then elevating it till the star appears exactly in its centre, which is indicated by two cross wires; the index now points out the elevation.

Meridian.—It only remains then to define the vertical in which the star is; and for this purpose some vertical must be selected, to whose position that of all the rest may be referred,—from which their distances may be estimated. Now, of all the verticals, that one, Z H N O, which is called the *meridian*, and which passes through the poles of the sphere, P p, is the most remarkable. The planes of them all pass through the zenith, Z, through the eye of the spectator, z, and through the centre of the earth, E; but that of one only, Z p O P, has the property of passing also through the two celestial poles, or through the axis, P p, of the sphere. This is the plane of the meridian. It is distinguished from every other vertical plane by another important circumstance. The diurnal circles, l m n, 1 *h* 2, which the stars describe, have their planes parallel to each other, and perpendicular to the axis of the sphere, P p. They are in general termed *parallels*; and that one, e E q, which also passes through the centre of the earth, is termed, as we have already seen, the *equator*, being equally distant from both the poles. The plane of the meridian, as it passes through the vertical, Z N, is perpendicular to the horizon, H O; and as it also passes through the celestial axis, it is also perpendicular to the equator, e E q, and to all the parallels, l m n, 1 *h* 2. From this peculiar position of these circles relatively to each other, the meridian divides into two equal parts that portion of each parallel which is above the horizon, as well as that portion of each which is below it, one half only of each of these halves being seen in the figure, l m 1 *h*. The instant, therefore, the sun passes it above the horizon it is *mid-day*, from which circumstance it derives its name—he has then attained his greatest elevation; and the instant he passes it below the horizon it is *mid-night*. It is the same with the stars; they all come to the meridian, and to their greatest elevation, at the middle of the interval between their rising and setting; and as to those stars which, from their proximity to the pole, never reach the horizon, but describe whole circles, *S S′*, s s′, above it, passing the meridian both above, at *S* s, and below the poles, at S′s′, the meridian divides these circles into two equal parts.

Transits.—Thus, for every one of the heavenly bodies, without exception, the instant of the passage, or *transit* as it is called, is that of the greatest altitude; and for those stars which pass the meridian both above and below the pole, it is the instant of their greatest altitude in the one case, and the least in the other.

Meridian line.—The position of the meridian is indicated by that of the sun at noon. It is more accurately determined by observations of his altitude, or that of a star, before and after passing the meridian. Observe with an instrument the altitude of a star some time before its passage over the meridian, and mark the vertical in which it then is. In descending, after its transit, the star will again arrive at the same distance from the horizon which was noted in its ascent. Its progress must, therefore, be carefully watched, in order to mark the vertical in which it is situated when this happens. The direction of the meridian is intermediate between that of the two verticals; and if a staff be set up in this direction it will mark out what is termed a *meridian line*. The east and west are the directions, each 90° from the former.

Azimuths.—It is from the meridian, then, the *prime* vertical, that the distances from the other verticals are reckoned. They are termed in general *azimuths*. The azimuth of a star, S, is the angle, H Z *h*, that the vertical plane in which it is situated makes with the plane of the meridian, the prime vertical; and is measured by the arc of the horizon, H *h*, intercepted between the point H, in which the meridian cuts the horizon, and the point *h*, in which the vertical Z S *h* cuts it. The azimuth then determines the vertical in which the star is, and its altitude, its position upon that vertical; and thus its situation, S, upon the sphere is completely ascertained.

Sometimes also the vertical Z E N, which is perpendicular to the meridian, and lies due east and west, is termed the *prime* vertical, and the position of a star's vertical, indicated by its distance from it, E *h*, which is termed its *amplitude*.

Celestial meridians.—But as the verticals and the

Of quantities

horizon change their position with that of the observer, the position of every star, were it indicated relatively to these circles, would have the inconvenience of being expressed by a different quantity for every different position upon the globe. These positions, therefore, are only useful as they are connected with, and afford the means, of determining those of the stars relatively to another and a similar system of circles, quite independent of our position upon the earth. In the latter, the axis of the celestial sphere, P p, Fig. 15. corresponds to the vertical, Z N, Fig. 14. in the former. A series of circles, Z H N O P, P e p, P e p, Fig. 15. whose planes pass through this axis, and which are called in general *celestial meridians*, correspond to the verticals, Z H N, &c. Fig. 14. The equator, E Q, Fig. 15. to which they are all perpendicular, is analogous to the horizon, H O, Fig. 14. and the meridian of the place is at once a vertical and a celestial meridian. It is that vertical, Z H N O, Fig. 14. whose plane passes through the axis of the sphere, and that meridian, P E p Q, Fig. 15. whose plane passes through the vertical of the plane, Z N.

The position of a star, S, relatively to this system of circles, is determined in the same manner, when we know the meridian, P e p, in which it is, and its distance, S e, from the equator, which gives the parallel, S O, in which it is. These are the two lines at whose point of intersection it is situated.

Position of the equator.—It is, first of all, necessary then to determine the position of the plane of the equator. This is done by finding that of the axis of the sphere, P p, to which that plane is perpendicular, and which is indicated by the position of the north pole, P. The pole being in the meridian, its position is determined by its altitude, O P. This could be easily measured, were there a star situated in the stationary point, P. There is none exactly so situated; the pole-star, however, describes a circle round it, at the distance of 2°, and the rest, *S*, s, at greater distances. The pole, then, the common centre of all these circles, must be situated half-way between the positions, s, s′, of any star when crossing the meridian, the one above, and the other below the pole, and must therefore have an altitude intermediate between the greatest, O s, and least altitude, O s′, of the star.

Altitude of the pole.—We have only, then, to fix upon a star which never sets, and observe its extreme altitudes, the one when it passes the meridian above, and the other when it passes it below the pole. The mean, that is half the sum of the greatest and least altitudes, is the altitude of the pole. If the instrument is not provided with a telescope for observing the stars through the day, these observations can only be made in winter, when the night being longer than the day, a star can be seen during more than one-half of its revolution.

The position of the pole being thus determined, the line joining it to the eye of the spectator is the axis of the sphere, and the plane of the equator is determined to a nearness by setting up a plane surface or board perpendicular to this axis. By looking along this board the eye will be directed to the celestial equator, the circle in which this plane, produced on all sides, would cut the sphere; and on the 22d of March and September, the sun, then describing this circle by the diurnal rotation, will be seen during the whole day in the direction of the board.

To obtain greater accuracy it must be observed, that the altitude of the pole, O P, together with the altitude of the equator, H Q, just amount to 90° (inasmuch as they are the two portions, O P, H Q, of the whole semicircle (180°) of the meridian, O P Q H, which remain after taking away the portion, P Q, between the pole and the equator, which measures the right angle Q e P.) They are each, therefore, what the other wants of 90°. They are the *complements* of each other, as this relation is termed. By taking the altitude of the pole, then, from 90°, the remainder is that of the plane of the equator; and the telescope of the instrument being set in the meridian to this altitude, will indicate the point in which the equator cuts it. The points due east and west are those in which it cuts the horizon, because it is perpendicular to the meridian; and thus the situation of this circle is completely ascertained by these three points.

Declination.—The distance, S *e*, of a star from the equator, or the distance of the parallel in which it is, is termed its *declination*. It is analogous to its altitude in the former system of circles; and as the meridian is common to both these systems, and thus measures both declination and altitude, the declination of a star is hence connected by a very simple relation with its meridian or greatest altitude. It is evidently the difference, *s* Q, or *s′* Q, between the meridian altitude *s* H, and the altitude of the equator, Q H, the complement of the altitude of the pole, and is north or south according as the star is north or south of the equator, or according as the meridian altitude is greater or less than the co-latitude of the pole. The declinations of the stars, then, are determined by measuring their altitudes when on the meridian.

To define, now, the meridian in which the star is, it is necessary, as before, to fix upon some one to form the zero of the scale, from whose positions that of all the rest may be reckoned, as the horizon, H O, Fig 14. is the zero of the scale of altitudes, the meridian, Z H, of azimuths, and the equator, E Q, Fig. 15. of declinations.

Equinoxes.—Right ascension.—Now we have seen that the ecliptic, the circle which the sun annually describes, crosses the equator at a certain obliquity; the intersection of these two circles mark two positions which can always be recognised in the heavens; they are called the equinoxes, because the sun being then in the equator, makes the days equal to the night all over the world. The line which joins them passes through the centre of the earth, and is called the *line of the equinoxes*. The sun is in the one, in the spring, on the 22d of March, and in the other, in Autumn, on the 22d of September. These are the days of the equinoxes, the former of the vernal, the latter of the autumnal equinoxes. It is that meridian which passes through the equinox of spring which has been selected to reckon the distance of the rest from; it is termed the *prime meridian*, and is represented in Fig. 15. by P Q p. The planes of all the meridians pass through the axis of the sphere, P p; that of the prime meridian is distinguished by also passing through the line of the equinoxes. The distance of the meri-

Of quantities dian, P S e, in which a star is from the prime meridian P Q, is termed its *right ascension*. It is the angle which the plane of the star's meridian, P e p, makes with the plane of the prime meridian, P Q p E, and is measured by the arc of the equator, Q e, comprehended between the prime meridian and the star's meridian—between the vernal equinox, the point in which the prime meridian cuts the equator, and the point, e, in which the star's meridian cuts the equator.

The situation of the prime vertical is always fixed for the same point of the globe; the prime meridian is continually moving along with the rest of the meridians, by the effect of the diurnal motion of the sphere; its position, as well as their right ascensions, is therefore not so easily determined, and it is here that the astronomer discovers the inestimable value of the time-piece, as an instrument for finding positions in space. The position of bodies which are at rest is determined by their distance from other bodies; but bodies in motion, as we have seen, describe time as well as space, some in a regular, and some in a very irregular manner. When the motion of a body is uniform, or its velocity is the same in every part of its course, it moves over the same number of feet every second of time. If we once knew this velocity, therefore, it would be easy, by observing the elapsed time upon the clock, to determine the distance of the body from the point at which it set out.

It is upon this principle that the astronomer measures the right ascensions of the stars. Their motion has been discovered to be perfectly uniform, or at any rate to excel that of the nicest instruments. Its rate is easily recognised by observing the transits of the stars over the meridian. These observations are made with what is termed a *transit* instrument. It is a telescope constructed to move with great precision in the plane of the meridian, and having in its field of view one or more fine wires parallel to the meridian, and equally distant from each other. The instant of the transit is marked by the instant of the stars covering the middle wire, or by the interval between the instants of its covering the extreme ones. The interval between two successive transits of the same star is termed a *sidereal* day; it is the period of the stars making a complete circuit in the heavens, and the astronomical, or *sidereal* clock, as it is termed, is so constructed, that the hour hand makes a complete revolution in the same time; so that if a star passes the meridian to-night when the clock indicates, for example, $0^h, 0^m, 0^s$, it will indicate exactly $0^h, 0^m, 0^s$, as the instant of the transit to-morrow night. The hand of the clock thus describing the same angle with the star in the same time, forms a reduced image of the star's diurnal motion, resembling it in every thing but the scale. Suppose, now, that the clock indicates $0^h, 0^m, 0^s$, for the instant of the transit of the star which is situated in the prime meridian, not only will it also indicate $0^h, 0^m, 0^s$, for the instant of its succeeding transit, so that by looking through the telescope at that time, we expect to find the star covering the centre wire with nearly as much certainty as the rising of the sun,—not only is this single position of the star indicated by the clock, but each new position which it assumes in advancing from the meridian towards the west, is indicated by the corresponding position of the hand as it advances from the origin of its scale, $0^h, 0^m, 0^s$. The interval of time from 0^h will thus indicate the distance of the prime meridian from the meridian of the plane, and for every star, the instant of its transit over the meridian of the place will indicate its right ascension,—the angular distance of the star's meridian from the prime meridian. But the angle which the star describes in a day, namely the complete circuit, is divided into 360^0, each degree into $60'$ &c. while the divisions of the circuit which the hand of the clock describes are fifteen times larger, the circumference being only divided into 24 hours, each hour into 60 minutes, &c. The arcs of the right ascension then, will be expressed in time by a quantity just fifteen times less than when expressed, as usual, by degrees of the equator. But whether the right ascension of the star be expressed in time or in angular distance, it is still the same quantity,—the angle between the planes of the prime meridian and the star's meridian; and it is the mere circumstance of time and angular magnitude which are both involved in the stars motion, being both measured by the portions of the circumference of a circle; it is the mere circumstance of these two quantities, apparently so heterogeneous in their nature, being still brought to a common measure, that enables us to express the right ascension by the one or the other indifferently.

To obtain the right ascensions of the heavenly bodies, then, it is first of all necessary that the clock move uniformly, for that is the point upon which the accuracy of the method entirely depends. Provided this condition be fulfilled, it is not of so much consequence its going a little faster or a little slower than the star, for this can easily be allowed for.

Position of the equinox.—The next thing to be determined is, the position of the prime meridian, that the clock may be set to $0^h, 0^m, 0^s$, when it passes the meridian of the place. This could easily be observed, were there a star situated in the vernal equinox; there is none exactly so situated, but the sun is in this point once a year, and would therefore answer the purpose were he at the same instant on the meridian. This, however, seldom happens, and it is only by an indirect process that we obtain the object in question. When the sun is in the equator, his meridian altitude being then the same with that of the equator, is evidently equal to the co-altitude of the pole or the co-latitude of the place. By observing his meridian altitude the day before and the day after his passing the equator, it is easy from these data to *compute* the time, suppose $3^h\ 40^m$, that elapses between his transit on the first day, and the instant of his crossing the equator, or the instant when his meridian altitude is exactly equal to the co-latitude of the place; the clock having been previously set to $0^h, 0^m, 0^s$, when a certain star, suppose west of the sun, comes to the meridian—the instant, suppose $6^h\ 10^m$ of the sun's transit the first day is also observed; this is the difference between the right ascension of the sun and that of the star; and adding it to the computed interval of $3^h\ 40^m$, their sum $9^h\ 50^m$, taken from 24^h, is the right ascension of the star, to which the clock must be set when the star

Of quantities

comes to the meridian, in order that it may indicate 0^h, 0^m, 0^s, when the prime meridian comes to the meridian. This process very well illustrates the nature of the prime meridian; it is not, as we have formerly observed, a real object, neither is its position indicated by any real object which we can at all times observe,—it is merely the imaginary and conventional origin from which all right ascensions are dated; it is only recognised in the spring by the sun's crossing the equator, and even the instant of this event we are frequently obliged to deduce from other observations.

Latitude and longitude.—There is still another set of circles to which the position of the heavenly bodies have been referred. The ecliptic, E C, Fig. 16. is here analogous to the equator and to the horizon in the above systems; an imaginary line, *P p*, perpendicular to the plane of the ecliptic passing through the centre of the earth, and meeting the sphere in two opposite points, *P*, *p*, corresponds to the axis of the sphere and to the vertical; it is the axis of the ecliptic; and a series of circles, *P* E *p* C, *P e p*, *P e p*, having this axis for the line of common section of their planes, correspond to the meridians and the verticals. These circles have received no particular name, except that of *secondaries* to the ecliptic, as the meridians are sometimes termed secondaries to the equator, and the verticals to the horizon. The points *P p*, in which the axis meets the sphere, are termed in like manner the *poles* of the ecliptic, as the poles of the sphere are sometimes termed the poles of the equator, and the zenith and nadir the poles of the horizon. The position of a star, S, is determined by that of the secondary to the ecliptic *P e p*, in which it is, and its distance *E e* on this secondary from the ecliptic. Its distance from the ecliptic is termed its *latitude;* and the distance, E*e*, of its secondary, from that which passes through the vernal equinox, is termed its *longitude;* it is the arc of the ecliptic comprehended between these two secondaries. The ecliptic has been (p. 489.) divided into twelve signs, each equal to 30°. In reckoning longitudes this division is used, and instead of saying a longitude of 30°, 45°, &c. we say 1 sign; 1 sign 15°,—or simply 1^s; $1^s\ 15^\circ$.

The latitudes and longitudes of stars are not observed; they are only computed from their right ascensions and declinations. The latter are determined, as we have seen, by observations of their meridian altitudes and their meridian transits. The meridian thus becomes the circle in which all astronomical observations are made. These observations are the source of all astronomical knowledge; and the transit instrument and astronomical quadrant for measuring altitudes, which is even sometimes united with the former, these, together with the clock, are the chief instruments of the practical astronomer, "the capital furniture of an observatory."

SECT. VI. *Positions on the Earth.*

For the purpose of determining the positions of places upon the earth's surface, a set of circles have been imagined quite analogous to one of those systems which we have described in the heavens. The axis, P p, Fig. 15. of the equator, which joins the two celestial poles, and passes through the centre of the earth, meets its surface in two points, P′, p′, opposite to each other. These are called the *terrestrial poles*, or *the poles of the earth.* The north terrestrial being next to the north celestial pole and the south to the south. The line P′ p′, which joins them, is also termed the *axis of the earth;* it is that portion of the axis of the sphere comprehended within the earth's surface. The planes of the celestial meridians, which all meet in the celestial and terrestrial axis, must in like manner meet the earth's surface, and their sections of it will be perfect circles if the earth be a perfect sphere, which we shall here suppose; they are termed *terrestrial meridians*; they are the circles P′ Q′ p′, P′ e′ p′, P′ c′ p′, &c. Fig. 15. or Fig. 17. diverging from the poles P′ p′, which a series of planes passing through the earth's axis would form upon its surface,—the lines according to which they would meet it. The plane of the celestial equator E Q, in passing through the earth's centre, forms upon its surface a circle E′ Q′, termed the *terrestrial equator*, or by mariners the *line.* It is the line according to which a plane passing through the earth's centre, and perpendicular to its axis, would meet its surface.

Of quantities

Parallels.—Lastly, there has been imagined a series of circles proceeding from the equator towards the poles, and having their planes parallel to that of the equator; they are analogous to the celestial parallels.

Tropics.—Four of the parallels are distinguished above the rest, namely two, T R, T′R′, Fig. 17. situated at the distance of $23\frac{1}{2}^\circ$ on each side of the equator, and other two, A C, A′C′, at the same distance from either pole; the two first being analogous to the celestial tropics, E T, C′T′, Fig. 16. are named accordingly, that which is in the southern hemisphere the tropic of Capricorn, and that in the northern the tropic of Cancer. The two circles near the poles are termed the *polar circles*, the northern being also termed the *arctic*, and the southern the *antarctic circle.* These four circles divide the earth into five compartments, or zones, A C P′, A C R T, R T T′R, R′T′ A′ C′, and A′ C′p′, which have received names from the climates by which they are distinguished; that between the two tropics, in the middle of which is the equator, being the hottest, is termed the *torrid zone*; those beyond the polar circles, where it is coldest, the *frigid zones*; and the intermediate belts, where the climate is equally the medium between these extremes, *the temperate zones.*

Latitude and longitude.—The position of a place, *P*′, Fig. 17. on the earth's surface, is determined in the same manner as that of a star, by two elements, the distance *P′ c′* of its parallel from the equator, and *c′* Q′, of its meridian P′ *c′* p′ from a first meridian P′ Q′ p′, fixed by convention to form the origin of the scale. The first is termed its *latitude*; it is the distance of the place from the equator,—the arc of the meridian comprehended between it and the equator; and the parallel circles are termed *parallels of latitude.* The second is termed its *longitude*; it is the arc of the equator comprehended between the meridian of the place and the first meridian,—the angular distance between the plane of the first meridian and that of the meridian of the place of which this arc is the measure. These terms are analogous, the one to the declination, the other to the right ascension, and must not be confounded with the latitude and longitude of a star. No meridian has been fixed upon for a universal first meridian. In this country the longitudes are reckoned from the meridian of London; in France from that of Paris; in Russia from that of Petersburgh, and so on.

The latitude of a place A, Fig. 20. being the angle A T e, or Z T E, contained between the vertical T A Z, and the plane of the equator T e E, is equal to the distance of the equator from the zenith E Z, which is also the complement of O P, the altitude of the pole. To find the latitude of a place, then, it is only necessary to measure the altitude of the pole by the method already described.

In the same manner the longitude of a place, A, Fig. 20. being the angle A P′ m′, between the plane of its terrestrial meridian P′ A p′ and that of the first meridian P, m′ p′, or between the plane of its celestial meridian P E p, and that of the celestial meridian of London P m p, may be measured by the arc m E of the celestial equator, contained between the two meridians, that is to say, the difference between their right ascensions, or the interval of time that elapses between the transit of a star over the one meridian and its transit over the other. If we knew, for example, to-night, the instant of a star's transit over the meridian at London, we could observe to-night the instant of its transit at Edinburgh, and the interval of time 12′ 48″, or 2° 12′, multiplying by 15 would be the longitude of Edinburgh, just as a person who knows at what hour the mail-coach leaves London, as well as its rate of travelling, can tell, by observing at what hour it reaches Edinburgh, the distance between the two cities, with this difference, that the rate of the star's travelling between the two meridians is infinitely more uniform than that of the coach between the two places.

It is upon this principle that depend all the methods which have been invented for discovering the longitude,—a problem so interesting to the navigator. Time is regulated all over the world by the successive arrivals of the sun at the meridian of the place, as he advances in his daily course from east to west; and as he can only be upon one meridian at a time, he can only arrive successively upon the meridians of different places, as a coach arrives successively and at different times at its different stages. The inhabitants of different places thus have their noon at different times, later and later than at London, as they are farther and farther towards the west; so that when it is noon at London, it is little more than half-past eleven at Dublin. At Philadelphia, 75° 13′ west, it is only seven o'clock in the morning; the sun may then only be rising at that city; and by setting a watch with the clock at London, it will be found, on crossing the Atlantic, to be five hours in advance of that of Philadelphia. The problem of the longitude is thus reduced to that of discovering the interval between the noon of London and the noon of the place, or in general the difference between the time reckoned at London and the time reckoned at the place. It is the great object of artists, accordingly, to produce time-pieces that may go with regularity, notwithstanding the motions of the vessel.

Distances of the heavenly bodies.—Such are the methods both of expressing and measuring the position of objects in the heavens and on the earth. But the heavenly bodies, as we have seen, are not all at the same distance from the earth; the moon is much nearer us than the sun; and the latter, probably, much nearer than the fixed stars. They are not, therefore, all upon the surface of a sphere, as we have supposed; and as the above methods only fix their angular positions, leaving their linear distance quite undetermined, as a star may clearly have the same right ascension and declination, whether it be at the distance of 10, 100, or any number of millions of miles;—this important element is still wanting to complete our knowledge of their positions in space.

This subject has interested astronomers in all ages; and they have endeavoured to discover these distances by all the methods which the progress of the science has successively indicated. But the principle of them all is the same as that by which we discover the distance of inaccessible terrestrial objects. To give greater accuracy to the operation, astronomers have contrived to take the semi-diameter of the earth itself, and even the earth's distance from the sun, as the *bases* of the triangles, the intersection of whose sides determines the distances of the stars. Thus, let E R, Fig. 18. be the earth's semi-diameter, and let the sun be at S; astronomers have contrived to measure the angle E R S, which gives at once E S R and the distance E S. This angle, E S R, is termed the sun's *parallax*; it is the angle which the earth's semi-diameter subtends at the sun. If the sun be in the horizon at the time of the observation, the angle E S R, which is then the greatest, is termed the sun's *horizontal parallax*. If S had been the moon, or any other heavenly body in the horizon, the angle E S R would then be its horizontal parallax, the angular magnitude under which the earth's semi-diameter would have appeared to a spectator at that body, and it is the angle of which the knowledge leads directly to that of the distance of the body. But in the cases of the sun, the moon, and most of the planets, which have all a sensible apparent diameter, the variation of their distances from the earth is obtained with great facility by measuring their apparent diameters, that is, the angles which their real diameters subtend at the earth, and which augment and diminish in proportion as the objects approach to or recede from the earth. Thus, at the earth, E, Fig. 19. the angle S E U is the apparent diameter of the sun, and must not be confounded with its real diameter S U, which is invariable, and of which the apparent diameter is only the angular magnitude. If the sun advances into the position *S U*, or s u, his apparent diameter increases to the angle *S E U* and s E u, which, in small angles, is proportional to the distance from E. By measuring this angle, then, which is done with great precision by an instrument for the purpose, termed *a micrometer*, the variation in the distances of the heavenly bodies is ascertained.

Refraction, &c.—After all the above observations for determining the positions of the heavenly bodies are

The earth. made, there still remain several corrections, which must be applied before the *true* places, as they are termed, can be ascertained. Various causes, some optical, and some real, such as what are termed *refraction*, *parallax*, *aberration*, &c. contribute to produce, in their apparent places, a slight deviation from those which they really occupy. For these derangements, though only amounting, in many cases, to a few seconds, and though it has required the highest refinements of art to discover their effects, and of science to discover their causes, the astronomer is nevertheless careful to make the necessary allowances before making use of his observations; and since an observed deviation, were it but a few seconds, in any of the heavenly bodies, from the position either in place or in time which his calculation would assign to it, becomes thus a thing to be accounted for, some idea may be obtained of the wonderful precision to which the knowledge of these positions has been carried. It is so great, indeed, that if a telescope be directed to-day to a determinate point of the heavens, we can tell, several years in advance, the day, the hour, the minute, and the second, in which almost any one of the heavenly bodies will come and place itself exactly in the centre of the telescope, and cover in it a thread finer than a hair. The errors of astronomical tables are actually comprised within the breadth of this thread.

CHAP. II. OF THE EARTH.

SECT. I. *Its Figure.*

We have already seen, that the regularity with which new stars make their appearance, shews the convexity of the earth to be pretty regular in that direction. A more correct knowledge of its figure will be obtained by actually measuring, with the precision of modern observations, the exact dimensions of the portions of the heavens which successively make their appearance as we advance a certain distance towards the north or south.

Oblateness.—Upon these principles, portions of the terrestrial meridian have been measured in various parts of the world, some of them with astonishing precision, and to the extent, in France, of 12°, or one 30th of the circumference; and the result indicates incontestibly, to the figure of the earth, like that of an orange, a degree of oblateness at the poles, and a protuberance at the equator; so that the axis of the polar diameter is to the equatorial diameter as the proportion of 319 to 320, and less by about 24 miles.

Variation of gravity on its surface.—The oblateness of the earth is also manifested by the diminution of gravity on the weight of bodies, as we advance from the centre of the earth. It has been found, that as we ascend to the tops of high mountains, the effect of gravity suffers a sensible diminution. This result could not be obtained by means of the most exact balance, as the intensity of the weights themselves are equally diminished with that of the bodies which we would weigh. It is only by experiments on the pendulum that these variations can be noticed. Its oscillations become slower, as gravity, the power which produces them, is diminished. In this manner the pendulum, vibrating seconds at the equator and at the level of the sea, was found, when carried to Quito, 9000 feet high, to make somewhat fewer than 60 vibrations in a minute. Since the pole, then, is nearer to the earth's centre than the equator, it should be expected that the pendulum would go slower at the one than at the other; and, accordingly, very numerous and exact experiments on the pendulum, in different parts of the world, have left no doubt of the certainty of this result. The earth.

Cause of its oblateness.—This oblate figure is exactly that which a round mass of stiff clay would assume on being turned rapidly round an axis. The effect will also be more easily exhibited, by fixing the point A, Pl.23, Fig.9. of an iron or steel hoop, A B C D, to the axis A C, the opposite point, C, being also attached to the axis, but allowed to slide freely up and down. On turning the axis, the point C will be observed to descend as the velocity of rotation increases; and the hoop will assume the oblate figure A b c d. This effect is produced by what is termed the *centrifugal* force. It is a tendency which all revolving bodies are found to possess, of flying from the centre of their revolutions, from which they are only preserved at a certain distance by the operation of some very powerful cause;—in ordinary cases, by the cohesion of the materials of which they are composed. This is very well illustrated by a sling;—no sooner do we slip the string by which the stone is confined, but it flies with all the velocity which it has been accumulating from the beginning of the rotation. The analogy between the figure of the hoop and that of the earth, leads naturally to the inquiry, if the resemblance does not extend farther,—if their figures are not also produced by similar causes; and as the earth may certainly contain within itself, like the clay, some principle by which its particles may yield, in a slight degree, to the tremendous impulse of the centrifugal force which the incessant and rapid rotation of such a huge mass of matter would necessarily call into action, its oblate figure is, therefore, in this view, no inconsiderable indication of its motion on an axis, which we have already had some reason to suspect.

SECT. II. *The Effects of the Sun's Light and Heat upon the Earth.*

Length of the days and nights, and variations of the seasons.—The sun, though some philosophers believe it is not the only, is certainly one of the principal causes of the heat which we enjoy; else there would not be so striking a connection between the inequalities of the days and nights, unquestionably the effect of the sun's position, and the vicissitudes of the seasons. It is curious to observe how all these phenomena are made to arise from a single circumstance. We have already seen, in general, how the obliquity of the ecliptic is the cause of the inequality in the days and nights. It is equally the cause of the vicissitudes of the seasons. This obliquity has been found to be nearly $23\frac{1}{2}°$; and as this circumstance of the sun's not continuing always in the plane of the equator (p. 488.) but receding from it alternately towards the north and south poles, is the only one cause which produces these effects, we shall for a moment abstract en-

The earth. tirely from the sun's motion from west to east, and suppose (what by the way seems at first sight really the case) that besides his diurnal motion from east to west, he has also merely a reciprocating motion from north to south, and again from south to north. Thus, let P E p Q, Pl. 23. fig. 1. represent the earth, and *s* S s a portion of the celestial meridian, bounded by the two tropics, situated each at the distance of $23\frac{1}{2}^{\circ}$ from the equator S Q E, and between which the sun S is supposed continually to oscillate from *s*, the tropic of Capricorn in winter, to s the tropic of Cancer in summer, and from s back again to *s*, having crossed and re-crossed the equator S, and finished the year, the period of these variations.

As a candle only enlightens one half of a ball held at some distance from it, in the same manner the sun illuminates but one half of the earth at a time, the opposite one remaining in darkness. Now the boundary between light and darkness,—the line which separates the enlightened from the dark hemisphere, is termed the *circle of illumination*. To the whole of the inhabitants, on one side of this circle it is day, and to the whole of the inhabitants on the other it is night.

This circle, always perpendicular to the direction of the sun's rays, necessarily changes its position along with the sun. When the sun is in the equator, at S, it passes through the two poles P p; and if we ascribe the diurnal motion to the earth's rotation, and not to the sun, (the appearances being the same in either case,) it will retain nearly the same position in the course of a day, and the vicissitude of day and night will be produced by the places on the earth successively plunging below this circle into the hemisphere of darkness, and rising above it into the hemisphere of light. But when the sun arrives at either of the tropics, as in Figs. 2. 3. the circle of illumination also arrives into the position A C, Fig. 2. or A C, Fig. 3. touching the opposite sides of the opposite solar circles, A C, a c. When the sun is at the equator, therefore, the circle of illumination will extend from pole to pole; and as it will be perpendicular to the equator and to all the parallels, it will divide them all into two equal parts. By the effect of the diurnal motion, then, every place will remain just as long in the hemisphere of light, P Q p, as in the hemisphere of darkness, P E p; and the days will thus be equal to the nights all over the world.

The arrival of the sun at either of the tropics considerably alters this state of things. The circles of illumination, Figs. 2. and 3. will then touch the opposite extremities of the arctic circles A C, a c; the enlightened hemisphere will now include the north frigid zone, A P C, Fig. 2. and exclude the south a p c, or include the south and exclude the north, as in Fig. 3. according as the sun in June is north of the equator, at the tropic of Cancer, or south of it, at the tropic of Capricorn, in December. In the middle of June, then, as the revolution of the earth can never bring the inhabitants of the north frigid zone within the hemisphere of darkness, nor the inhabitants of the south frigid zone within the hemisphere of light, the one will have a continued day and the other a continued night. At the equator, however, intermediate between these two extremes, this change in the sun's position will have no effect whatever upon the length of the days and nights, for as the circle of illumination still divides the equator into two equal parts, it will still be equally divided between light and darkness, and the days will still be equal to the nights. Between the equator and the frigid zones, the inhabitants of the different countries will have their days so much longer than their nights, or their nights longer than their days, in proportion as they recede from the equator towards the poles—in proportion as the arcs of their parallels, *a b*, *c d*, are more and more unequally divided between light and darkness, as their distance from the equator increases. In the middle of December, the situation of things is, in every particular, the reverse of this.

It thus appears, that in whatever part of his circuit the sun is, the day is uniformly equal to the night at the equator. As the sun advances towards the north, the circle of illumination recedes from the two poles, lengthening the days in the northern hemisphere, and shortening them in the same proportion in the southern, wholly including the countries round the north pole, which thus begin to have a continued day, and wholly excluding those round the south, which thus begin to have a continued night. When the sun arrives at the tropic of Cancer, which happens about the 22d June, it is then the summer solstice to the countries on the north of the equator beyond the tropics, and the winter solstice to those of the south; the whole of the north frigid zone has days without nights; the whole of the opposite has nights without days; all over the north temperate zone the day is the longest of the year, and all over the south the shortest; and these changes having thus attained their *maximum*, begin to occur in the reverse order, till the sun re-enters the equator on 22d September, the day of the autumnal equinox. Advancing now towards the south, the sun begins exactly to reverse the order which he had produced in advancing towards the north, till he arrives at the tropic of Capricorn on the 22d December; these changes then recommence in the opposite direction, and continue till the equinox of spring, when, as usual, the day is equal to the night all over the world.

Such is the constant progress of the sun, of the days, and of the seasons. Several causes, however, tend to diminish the long obscurity of the polar regions. The least visible portion of the solar disk being sufficient to produce the day, this circumstance adds several days to the time when the sun is visible under the polar circles, because that, after his upper limb reaches the horizon, it is several days before his whole disk is above it. Refraction augments still farther this effect, particularly in the cold countries, where the air is very dense. This was observed in 1597, by three Hollanders, who, having advanced to 84° 0′ north latitude, were stopt by the ice, and obliged to pass the winter at Nova Zembla. After three months of continual night, the cold having become terrible, the sun appeared for a moment at mid-day above the horizon, four days sooner than they had expected it at this latitude, and he continued from this time to rise by degrees.

The twilight also is much longer there than with

The earth. us; twilight comes almost in every part of the earth, when the sun has got 18° below the horizon. Now, to a spectator at the pole, who has in reality the equator for his horizon, the sun would never be 18° below his horizon till he had 18° of declination,—till he had advanced 18° on the other side of the equator, but he never advances beyond $23\frac{1}{2}$°, his greatest declination; the twilight, therefore, will never cease but during the short interval in which the sun moves from 18° of declination to the tropic, that is, to $23\frac{1}{2}$° of declination, and from the tropic back again to 18°; this is about 70 days. So that, on this account, there will only be 70 days of total darkness at the pole, though the sun disappears for six months; and this interval is much less nearer the polar circles.

Besides this, when the moon is north of the equator, she is constantly above the polar horizon.

In fine, a great number of meteors, such as *aurora borealis*, and globes of fire, diffuse their light in those desert regions.

Climates.—The quantity of heat which any place on the earth derives from the sun is greater the longer he continues above the horizon; it also depends upon his elevation. Every one knows, that in the morning, as the sun rises higher and higher in the sky, the day becomes hotter, and as he descends in the afternoon the heat declines in the same manner. The same cause operates at different places throughout the year, by the sun's rising to different elevations; and the effect is greatest at the equator, decreases towards the north and south, and is least of all at the poles. As the sun's declination at the equator never exceeds $23\frac{1}{2}$°, his meridian altitude is never less than $66\frac{1}{2}$°, and his rays are therefore never very far from falling quite perpendicularly upon the surface of the ground, while at the poles his altitude never exceeds $23\frac{1}{2}$°, and his rays are thus never very far from falling quite parallel upon the surface. By the combined effect of these two causes it is found, that, if the whole heat received at the equator be 100, the whole heat received at the pole is only 40; between these extremes it varies by regular gradations, and in the parallel of 45° amounts to 73; and this is one powerful cause of those remarkable varieties in the climate of different countries, from the equator towards the poles. It is on this account that the heat is so excessive in the torrid zone, and the cold in the frigid zones, that while the beauties of nature are scattered with the utmost profusion in the one, the others are barren and almost uninhabitable, and that the countries, such as Europe, in the temperate zone preserve a happy medium between these extremes.

Sect. III. *On the Tides.*

When we consider how invariably every motion which we are able to produce on the earth terminates finally in rest, we are apt to imagine that rest is the natural state of bodies, and to enumerate among their properties that of sluggishness, inactivity, or *vis inertiæ*, as it is termed. The celestial bodies seem to present an order of things the very reverse. As they are continually changing their position, activity seems to belong to them in a much greater degree than sluggishness to the bodies on the earth, and the matter of which they are composed is thus apparently of a different nature. What are we to think then, of the perpetual movements of the ocean, which changes its figure every instant of the day, by regular and periodical oscillations, known by the name of the *tides*. "It is a circumstance truly astonishing," says La Place, "to behold, even in calm and serene weather, the intense agitation of this great fluid mass, whose waves constantly break with impetuosity upon the shore. This phenomenon gives rise to reflection, and excites a strong desire to penetrate the cause." The following are its appearances. Of motions.

Twice every day the waters rise in our harbours, inundate our shores, and ascend our rivers to great distances, and with great rapidity. This *flux* of the tide continues with accelerated velocity for three hours; it then gradually diminishes, and in three hours more ceases altogether; this is *high-water*, or *high-tide*. The waters having now attained their greatest elevation, the tide *turns*, *the reflux* begins, and the whole mass of the ocean moves for six hours more in the contrary direction; it is then *low water*. The waters have now attained their greatest depression; and, after a short interval of repose, the intermediate step in every motion which reverses its direction, the tide again turns, runs for six hours in the same direction as at first, and again for six hours in the opposite.

The slightest observation is sufficient to shew, that these variations are connected with the moon, as they follow her motions with wonderful regularity. The moon, as we have seen, rises later and later every day, until the end of the month, when she again rises nearly about the same hour as at first. The time of high-water happens also, until the end of the month, later and later every day, and in this manner performs the complete circuit, (if we may be allowed the expression,) of the 24 hours, in the same time that the moon performs the complete circuit of the heavens.

The sun has also a sensible connection with the tides; for when the moon is in conjunction, the oscillation of the ocean is then the greatest, the tides being then invariably highest at high-water and lowest at low-water; it is then *spring-tide*. When the moon is in opposition, the tides are then lowest at high-water and highest at low-water, and it is then *neep-tide*. This connection has been traced in all its details, and for almost every inequality in the motions or in the distances of the sun and moon, a similar inequality has been found in the motions of the ocean and in their intensity; there can hardly be a case, therefore, where we could say with more propriety, that the one is the *cause* of the other.

It thus appears, that the earth is intimately connected with the bodies in the heavens, and probably, therefore, forms a part of the same system. But the heavenly bodies are continually in motion,—Can we believe, then, that the earth is in complete repose?

Chap. III. Of the Motions common to all the Heavenly Bodies.

We have already discovered one motion, namely the diurnal, to which all the heavenly bodies, without any exception, are subject. There is another of the

Of motion. same kind, which, on account of its slowness, is not so easily observed, but whose accumulated effect is rendered quite sensible by comparing ancient with modern observations.

Since the time of the ancient astronomers, its effect is visible to the naked eye; for the pole star, which is now within 2° of the pole, was far distant from it in the time of Hipparchus, who was the first to notice this curious motion, and who was thence led to set down in a catalogue the positions of the stars, that posterity might be thus enabled to recognise any change in their positions. The event proved the utility of this bold project, as it is from his observations that the mean quantity of this motion is still deduced. Thus, Hipparchus, 128 years before Christ, found the longitude of the star *spica virginis*, 5*s*. 24° 0′; and in 1750 it was 6*s*. 20° 21; so that in 1878 years its longitude had increased no less than 26° 21′, more than $\frac{1}{15}$th of the whole circumference. Now the longitude of a star is its distance, reckoned upon the ecliptic, from the vernal equinox. Either then the above star must have advanced slowly from the vernal equinox towards the east, or the equinoxial point itself, in consequence of some change in the positions of the equator, or ecliptic, of which circles it is the point of intersection, must, on this account, have retrograded from the star towards the west. But this motion is found in all the stars, without any exception; it is natural, therefore, to ascribe it rather to a regression in the equinox itself; and accordingly it has been termed the *precession of the equinoxial points*, or *of the equinoxes*.

The next object was to discover whether this precession belonged to the ecliptic or the equator; and it has been found, by comparing together a variety of observations, that while the latitudes of the stars, or their distances from the ecliptic, remain always nearly the same, their increase of longitude is accompanied by an increase of right ascension in all of them, and of their declinations or distances from the equator, by a small increase in some, and decrease in others. In short, all the appearances are represented by supposing either the celestial sphere, or the earth itself, to have a compound motion, of which the diurnal is only one of the elements. In the first case, the earth, c, (Plate 23. Fig. 4.) along with the axis of the equator, P p, would remain at rest, and the sphere, P E p Q, would not only revolve once a day on the axis, P p, of the equator, E Q, and in the direction E c Q, from east to west, but, at the same time, would have also a much slower motion upon the axis, *P p*, of the ecliptic *E* C, and in the opposite direction, *E* c C, and not completing a revolution in less than 25,000 years.

By the effect of this motion, different stars will occupy the position of the north pole in different ages; in 13,000 years the pole star, which is now only two, will be more than 40° from it; and the sphere will thus seem in different ages to perform its diurnal rotation on very different points.

But this motion is equally represented by ascribing it to the earth, whose axis, P′ p′, Fig. 4. always corresponding to the same point of its surface, and quite exempt from any diurnal motion, would nevertheless, have upon its centre, c, a slow conical motion round an axis, *P′ p′*, passing, when produced, through the poles of the ecliptic, *P p*. By the effect of this motion, the poles, P′ p′, would correspond successively to different parts of the heavens, and thus the same appearances would be produced, but unquestionably in a much simpler manner.

The sun.

Chap. IV. Of the Sun.

Sect. I. *Distance and Magnitude of the Sun.*

Distance.—When we attempt to find the sun's distance from the earth, by observing his position at the same instant from different places, it is found to be so great, and his horizontal parallax so small, as not to be determined in this manner with any degree of exactness. All that can be discovered from it is, that this distance is at least 6000 diameters of the earth. The observation of what are termed the *transits of Venus* over the sun's disk, affords the means of determining his parallax with much greater precision; and in this manner it has been fixed at 8″ 7, and his distance at 95 millions of miles.

Magnitude.—At this distance we are certain that the earth would appear under an angle of no more than 17″, and the mean apparent diameter of the sun is 32′ 3″. Hence, as the volumes of spherical bodies are as the cubes of their diameters, the volume of the sun is at least 200,000 times greater than that of the earth.

Sect. II. *Motions of the Sun.*

We have already found, by abstracting entirely from the sun's diurnal motion, that he appears to revolve round the earth once a year, in a plane which is inclined to the equator at a certain obliquity. But one body may move in a plane round another in a variety of ways. The sun may continue always in the same plane, while he may move in a circle, in an ellipse or oval, or in any other re-entering curve, of which the earth also may occupy either the centre or any other point. The sun may also move in his path in a regular or an irregular manner. All these things can only be determined by measuring with greater exactness his positions at different times of the year, and comparing them with each other.

For this purpose his meridian altitude, and the interval of time between his passage and that of a star over the meridian, are observed with extreme precision every day. From the one is deduced his declination, from the other his right ascension. These data give us a complete series of his longitudes, or of his angular positions on the ecliptic; and one element more, namely, his distance from the earth, is only necessary to complete our knowledge of his positions in space. To the above observations, therefore, are joined those of his apparent diameter, and we are thus enabled to delineate the series of points which the above angular and linear distances determine, and to exhibit, by their union, a reduced plan of the solar orbit. In this manner may the sun's path be recognised, by observations continued for a single year. But it was only by successive approximations that the discovery was first made, and this process may perhaps better illustrate the nature of the motion.

The sun.

If the sun move uniformly round the earth as a centre, his distance from it, and his velocity, should be always the same; but very sensible variations are observed in his apparent diameter, the index of his distance, as well as in his daily motion in longitude, the measure of his velocity,—the difference between his position to-day and his position to-morrow. On the 1st of July, for example, his diameter was found to be 31′ 31″, and on the 1st of January 32′ 35″ .6, while he moved from the 1st to the 2d of July 57′ 13″ in longitude, and from the 1st to the 2d of January 1° 1′ 11″. Neither his distance, therefore, nor his velocity, is constant, and he cannot move uniformly in a circle of which the earth occupies the centre.

But by ascribing to the earth an eccentric position, the sun might still retain his uniform circular motion, and at the same time exhibit variations both in distance and velocity. For at the point S, Pl. 23. Fig. 5. in the circle S A s, he would be nearer to the earth E, than at the point S, by twice, E C, the earth's distance from the centre C; while, on account of this proximity, his velocity at S, though really the same, would appear greater than at s; the space S 1 which he describes in a day at s, though really equal to s 1, which he describes in a day at s, would appear to a spectator on the earth to be magnified in the exact proportion of the distance E s to E S, in the proportion of his apparent diameter at S, to his apparent diameter at s. Let us see, then, if this proportion actually holds. His apparent diameter on the 1st of July and on the 1st of January, were to each other as 31′ 31″ to 32′ 35″ .6; that is, as 1 to 1.0339, while his corresponding velocities were to each other as 57′ 13″ to 1° 1′ 11″, that is, as 1 to 1.0693, instead of being as 1 to 1.0339. The same proportion is observed in every other part of his orbit. The sun, therefore, cannot move in a circle at all; and the last supposition, though it more nearly represents the appearance, is still far from the truth.

By proceeding in this manner, from one hypothesis to another, it was at last discovered by the celebrated Kepler, that a single and very remarkable law connects together these distances and velocities. He found, that while the sun's distance from the earth increases, his velocity diminishes in a ratio only half as great, that is to say, if his distance at any point of his course be 1, and his velocity 1, then, if his distance at any other point were 2, his velocity would be $\frac{1}{4}$, and if his distance were 3, his velocity would be $\frac{1}{9}$. From this it follows, that if a line E S, Fig. 5. termed the *radius vector*, be conceived to join their centres, and to be carried round the earth by the revolution of the sun, *the areas described by the radius vector, are always proportioned to the times of description*. Thus, if S 1 2 3, be the position of the sun in successive days, then the areas S E 1, 1 E 2, 2 E 3, &c. are all equal, being described in the same time; and the areas S E 1, S E 2, S E 3, &c. are proportional to S 1, S 2, S 3, &c. the times in which they are described. This law is termed *the first law of Kepler*.

Now the curve called the ellipse is the only one which satisfies the conditions of this law,—is the only one in which one body can move unequally round another, and describe by its radius vector, areas proportional to the times. Hence is deduced the *second law* of Kepler, *that the solar orbit is an ellipse of which the earth occupies one of the foci*.

The sun.

The ellipse is that curve which is described by fixing upon two immoveable points, F *f*, Fig. 6. the extremities of a thread, F A′ *f*, a pencil A stretching the thread to the position F A *f*, and sliding along it, then traces the ellipse A B E D. The immoveable points F *f*, are termed the *foci* of the ellipse. The line B F *f* D which joins them, and being produced both ways, terminates at the curve in the parts B D, is called the greater axis of the ellipse. It is the direction in which the curve is elongated, and is evidently equal to the length of the thread. The line A C E, drawn through the centre C, perpendicular to the greater axis, and meeting the curve in the points A E, is the lesser axis. It is round the earth, situated in one of the foci E, Fig. 7. that the sun seems annually to revolve in the course P B A. The point P, in which he is nearest the earth,—where his apparent diameter also, and his velocity, are the greatest, is termed the *perigee*. The opposite point A, where he is farthest from the earth, and where consequently his diameter and velocity are the least, is termed the *apogee*. At the intermediate point, B, his distance is a mean between his greatest and least distances; it is then equal to A C, the half of the greater axis A P. The distance C E, from the centre to the focus, is termed the *eccentricity*. It is evidently equal to the difference between A E, and A C, equal to the excess of his greatest above his mean distance. The smaller the eccentricity of an ellipse, or the smaller the distance between its foci, the nearer does it approach to a circle, which is its form when the eccentricity becomes nothing,—when the two foci are united in the centre of the ellipse.

The solar ellipse, in form, differs but little from a circle. The eccentricity amounts to little more than one-sixteenth of the mean distance; but neither its form nor its position remains always the same. They are subject to slow changes, which are only rendered sensible by the comparison of distant observations, and are termed *secular inequalities*. Since the period of the most ancient observations, the eccentricity has been diminishing; and at a rate which, if it were to continue uniform, would change the sun's orbit into a circle, and his unequal into a uniform motion, in about 36,000 years. The position of the orbit is fixed by the inclination of its plane to that of the ecliptic, and by the inclination of the greater axis to the line of the equinoxes; that is, by the longitude of the apogee or perigee. Now the orbit is found to approach by insensible degrees to the equator, and the longitude of the apogee to be continually increasing; so that if A P, Fig. 8. be its position in one age, A′ P′ will be its position in another; the secular diminution, or the diminution in a century, of the obliquity of the ecliptic, is 12″, and the secular progression of the axis relatively to the fixed stars is 19′ 4″.

The elliptic motion, however, even with all these variations, does not exactly represent modern observation. Their extreme precision has indicated small inequalities, of which the laws have only been developed by the discovery of their cause.

The sun.

Sect. III. *Measures of Time.*

The events indicated by the motions of the sun have been universally adopted for the standard measures of time. The intervals that elapse between his successive arrivals at the same equinox, form the years; and the intervals between his successive arrivals upon the meridian, form the days.

Days.—In civil life, the day is the interval between the rising and setting of the sun, and the night the period of his continuance below the horizon. What is termed the *solar, or astronomical day*, is the interval between two consecutive noons, or midnights,—between the instant of the sun's transit to-day, and the instant of his transit to-morrow. When time-pieces were introduced, and came gradually to be improved, a variation was perceived in the length of the solar days. The clock was found not to keep exact pace with the sun; and the nicer its construction, the more clearly did it indicate this inequality.

Mean time.—Since the solar day, then, is not always of the same duration, it is necessary to adopt another which shall have this property, and with which our clocks may correspond. For this purpose astronomers have adopted that which is termed the *mean* solar day, its length being a medium between all the solar days in the year. The time measured by these mean days, is called *mean time*; that measured by the true solar days, *true, or apparent time.* Apparent time is that which is indicated by a sun-dial; but it is according to mean time that all our clocks are regulated, and all our reckonings made. As the beginning and end, however, of the mean, is not indicated by any phenomenon, as that of the true day is by the solar transits, the clock can still only be regulated to mean time by observing the instant of the sun's transit, and applying to it the difference between the true and the mean time, which is found by calculation.

Equation of time.—This difference is called *the equation of time.* It is the number of minutes and seconds by which the noon of a well regulated clock ought to precede or follow that of a dial. It is set down on a table for every day of the year; and to regulate a clock, it is only necessary to set it, so that when the sun crosses the meridian, the hand of the clock may be distant from the hour of XII, either before or after it, by a quantity equal to the equation of time for that day, as shown in the table.

Two causes contribute to produce this inequality in the solar days; the unequal motion of the sun in his orbit, and the inclination of that orbit to the equator.

Years.—The revolutions of the sun, from any point to the same point again, are in general termed years, of which there are several kinds, namely; 1. The solar or *tropical year,* which is the interval between the successive arrivals of the sun at the same tropic; 2. The *sidereal year,* the interval between his arrivals at the same star, which consists of $365^d\ 6^h\ 9'\ 11''$; and, 3. The *anomalistic year,* the intervals between his arrivals at the apogee or perigee, which consists of $365^d\ 6^h\ 14'$.

Kalendar.—It is the tropical year which regulates the return of the seasons; and as it does not contain a complete number of solar days, the mode of adjusting the kalendar is somewhat complex. For this purpose, the exact length of the year,—the number of days, hours, &c. that elapse between two consecutive arrivals of the sun at the equinox must be known. But the year is not always of the same duration any more than the day. It is subject to an inequality, of which, as it depends upon the precession of the equinoxes, the period is 25,950 years; and the length of the mean solar year, by which the kalendar is regulated, is the medium between that of all the years of this period. By comparing ancient with modern observations, its length has been found 365 days, 5 hours, 48 minutes, 50 seconds.

If the length of the year were reckoned exactly 365 days, it would produce no inconvenience for two or three years; but in four years the error would amount nearly to a day, and we would then begin the new year a day before the other was ended. The error, however, would continually accumulate; and after a certain period, the beginning of the year would correspond successively to every day of spring, summer, autumn, and winter. To avoid this inconvenience, we make every fourth, or leap year as it is termed, consist of 366 days; and this addition of a day is termed *intercalation.* But the error does not amount exactly to a day in four years; hence another correction is necessary at the end of a century, when the leap year consists of only 365 days; and to obtain still greater accuracy, a third correction is applied at the end of four centuries, when the secular leap year is made, like the rest, 366 days. In this manner the days of the year are made to correspond with the days of the seasons for any length of time, and with the greatest exactness.

Sect. IV. *Nature of the Sun.*

Spots.—At such an amazing distance, it seems vain to hope that we shall ever discover the nature and constitution of the sun. The indefatigable labours of modern astronomers have nevertheless led to some curious results regarding it. The face of the sun, when viewed with a telescope, though of a bright and intense light, far above that of any other object, is often marked with dark *spots,* which, when examined from day to day, are found to traverse the whole surface, from east to west, in the space nearly of 14 days. The number, magnitude, and position of these spots are extremely variable. Sometimes they are so large as to be seen through a dark glass with the naked eye. In the year 1779, Dr Herschel perceived one about 50,000 miles in diameter,—more than six times the size of our earth. When a spot is first discovered on the eastern limb, it appears like a fine line; its breadth augments as it approaches the middle of the disk, from which it diminishes as it goes over to the western limb, where, at last, it entirely disappears. The same spot, after 14 days, is sometimes discovered again on the eastern side. It is not often, however, that this happens, as the spots during that period disappear, leaving sometimes behind them a superior brightness or luminous spot, termed a *facula,* in the position which they had occupied. Many of the spots disappear altogether in the course of a few days. Sometimes a number of

The sun.

small spots unites into one large spot; at other times a large spot separates into a number of small ones, which soon entirely disappear. The central portion or dark nucleus of a spot, is usually surrounded with a *penumbra* or fainter shade, and both the nucleus and the penumbra are almost perpetually changing their appearance. When Dr Long was examining the sun's image, received upon a sheet of white paper, he observed a large round spot divide itself into two, which receded from each other with immense rapidity. The Rev. Dr Wollaston also observed a spot to burst in pieces, like a mass of ice thrown upon a frozen pond.

As might have been expected, the opinions of astronomers are divided concerning these singular appearances. According to some, the spots indicate an abatement, previously to a general extinction of the great conflagration which had hitherto raged with unabated fury upon the sun. Some suppose them to be elevations or islands, which appear and disappear by the flux and reflux of an ocean of liquid fire; while others consider them merely as the scum which floats upon the surface of this immense fluid mass. La Place conceives them to indicate vivid effervescences, of which our volcanoes form but a feeble representation. But Dr Wilson, of Glasgow, was induced, by his own observations, to reject entirely the notion of the sun's being an igneous body. The observations of Dr Herschel, with the most powerful telescopes that have ever been contrived, lead him to support a similar theory, and even to hazard the opinion of the sun's being a habitable world. The sun, he supposes, consists of a dark, solid nucleus, surrounded by two strata of clouds, from the exterior of which proceed that heat and light which extend to the remotest extremities of the system, while the interior stratum serves to screen the inhabitants of the centre from the fury of the element which rages around them.

This theory is certainly liable to many objections, and others have been accordingly proposed with the view of obviating them; but the want of facts is a bar to any just theory upon the subject. That great changes are continually going on at the surface of this enormous mass can hardly be doubted; but the nature of these stupendous operations, on account of the distance at which they take place, must probably continue for ever unknown. A connexion has been supposed to exist between the appearance of the spots and the heat which the sun emits; but the grounds of this opinion are not considered by all as fully satisfactory.

Rotation.—Whatever be the nature of the spots, they have made us acquainted with a remarkable phenomenon, *the rotation of the sun upon an axis.*

By observing their successive positions, it is found, that the paths of different spots are always parallel and similar to each other, but that they are all subject to change of figure, which, as they go through all their variations, and are regularly repeated every year, are evidently connected with the positions of the sun. They are all completely represented, by supposing the spots to be attached to the spherical surface of the sun, and to revolve along with him in a certain period, and on an axis inclined at a certain angle to the ecliptic; and as no fact has been discovered at variance with this hypothesis, it can hardly be doubted that this is really the case. The axis of his rotation has been calculated, from these observations, to be inclined to the plane of the ecliptic at an angle of 7° 20′, and the period of his rotation to be $25^d\ 5^h\ 56^m$. It is less than the interval between the successive appearances of a spot; but this arises from the rotatory motion of the spot being, to a spectator on the earth, combined with the sun's annual motion from west to east, which, being in the same direction with that of the spot, has the effect of protracting the instant of its reappearance.

The moon.

Chap. V. Of the Moon.

Sect. I. *Distance and Magnitude of the Moon.*

Distance.—The same method which was insufficient to determine with requisite exactness the parallax of the sun, discovers that of the moon, at a medium 57′ 39″, which gives the moon's mean distance at 240,000 miles.

Magnitude.—At this distance, then, the earth subtends an angle of 1° 51′ 18″; while the moon, at the same distance, subtends an angle only of 31′ 20″. Their diameters, therefore, are in the ratio of these numbers, or very nearly as 3 to 11; and the volume of the lunar globe is 49 times less than that of the earth.

Sect. II. *Motions of the Moon.*

By pursuing the same method which enabled them to recognise the motions of the sun, astronomers have discovered those of the moon. By observing her meridian altitude, declination, and apparent diameter, every day, the positions of a series of points are obtained, and their union forms a representation of her orbit. From these observations it has been found, that her motions exactly resemble those of the sun, but on a smaller scale. Like the sun, she approaches and recedes from the earth—goes quicker in one part of her course than in another. The line drawn from her centre to the centre of the earth, describes round it areas proportional to the times; and, in short, she moves in an ellipse of which the earth occupies one of the foci. The plane of the moon's orbit is inclined to the plane of the ecliptic 5° 8′ 49″; it cuts it, therefore, in two opposite points, as in Pl. 21. Fig. 17. These points are termed the *nodes*; and the imaginary line which joins them, the *line of the nodes.* The ascending node is that where the moon crosses the ecliptic in ascending towards the north pole; the descending node is the opposite one, where she crosses the ecliptic to descend towards the south. The position of the nodes is indicated by the moon having no latitude, or being in the ecliptic. Her mean distance, or half the greater axis of her ellipse, being one, the eccentricity is 0.055; but neither the form nor the position of her orbit remains the same. Like the orbit of the sun, it is subject to a very complicated motion, which is represented by decomposing it into several elements. 1st, It has an oscillatory motion upon its lesser axis, by which its inclination to the ecliptic is continually varying. 2d, It

The moon.

has a rapid motion of rotation round its focus, the earth, by which the apogee is made to describe, from west to east, a sidereal revolution in $8^y\ 312^d\ 11^h\ 11^m\ 30^s$, and which is easily recognised by observing the stars with which the moon is successively in contact, when she successively arrives at her apogee, or has successively her least diameter. And, lastly, It has another motion, by which the nodes perform a revolution among the stars, and along the ecliptic, in a period of $18^y\ 223^d\ 7^h\ 13^m\ 17^s$. The comparison of ancient with modern observations shews also incontestibly an acceleration in its mean motion, which, though little sensible since the most ancient recorded eclipse, will be developed in progress of time; but the discovery of its cause has anticipated these observations, and shewn, that after a certain period it will stop, and be converted into a retardation, and thus go on for ever.

The elliptic motion, however, is much farther from representing the true motion of the moon than of the sun. This motion is subject to a great many other irregularities; so that the ellipse, even with all the above changes in its figure and situation, is still only the mean orbit of the moon, to which the application of not one but many equations is still necessary to form the true motion. The knowledge of these equations is necessary for the construction of correct lunar tables, an object of so much importance since the idea was conceived of employing her motions for determining the longitude at sea.

The revolutions of the moon to different points, in general termed months, are of different lengths, on account of the motions of the lunar orbit. The *synodical* month is the interval between two consecutive arrivals of the moon in conjunction with, or in opposition to the sun; its mean length, as determined by a comparison with ancient and modern eclipses, is $29^d\ 12^h\ 44^m\ 2^s$. The *sidereal* of $27^d\ 7^h\ 43^m\ 11^s$, is the interval between the moon's successive arrivals at the same longitude with a star; the tropical, $27^d\ 7^h\ 43^m\ 4^s$; and the anomalistic, $27^d\ 13^h\ 18^s\ 37^m$, the interval between its successive arrivals at the apogee or perigee.

Sect. III. *Eclipses.*

We have already explained the reasons for ascribing the eclipses of the moon to the circumstance of her passing through the shadow of the earth, and the eclipses of the sun to her casting a shadow upon the earth, and thus depriving us for a time of his light. A more correct knowledge of the lunar motions has left no doubt of this result, by shewing that at the time of an eclipse the position of the moon coincides exactly with that of the body M, Plate 21. Fig. 16. which, casting behind it a shadow, *a b c d*, darkens the sun; and that the position of the earth's shadow coincides exactly with *e f g h*, which darkens the moon; so that the beginning and end of these phenomena can be predicted to less than a minute for a great many years in advance. For this purpose it is only necessary to find, from the lunar and solar tables, when the moon and the earth have such positions relatively to the sun as ultimately to deprive each other of his light.

It is obvious that no eclipse can happen but when the centres of the sun, the moon, and the earth are almost, if not altogether, in one straight line. Thus, if the moon, in her monthly revolution, never approached nearer than at M′, Fig. 16. to the line S E, which joins the earth and sun S, its shadow, whatever might be its range, would go quite beyond the earth, and in like manner the shadow of the earth would go quite beyond the moon at m; but as the centre of the moon, when she is either beyond the earth, or between the sun and the earth, approaches the straight line, S E, its shadow, if long enough, will fall more and more upon the earth on the one hand; and she would herself enter farther and farther into the shadow of the earth on the other. To produce an eclipse, then, it is necessary that the sun and moon be either at least very nearly in the same, or very nearly in the opposite direction relatively to the earth.

By calculating the positions and magnitudes of the sun and moon it is found, upon the whole, that when the moon in opposition is about $12\frac{1}{2}^\circ$ from the node, there can be no lunar eclipse, and when less than 9° distant from it there must be one; and also that if the moon in conjunction is within $17^\circ\ 21'$ of the node, there may be a solar eclipse,—if it be more distant, there can be none.

If the distances, then, of the new and full moons from the nodes are without the *ecliptic limits*, there will be no eclipse; and if within them, an eclipse will certainly happen, of which the time, duration, &c. may be calculated according to the directions which usually accompany the tables.

A very near approximation, however, to the time of an eclipse is discovered with facility, by means of the famous period of 18 years $10^d\ 7^h\ 43^m$, at the end of which period the sun and moon, recommencing very nearly the same series of positions that they had before, all the eclipses of the sun and moon recur nearly at the same time.

Sect. IV. *Nature of the Moon.*

The phenomena of eclipses prove incontestibly that the moon is, like the earth, an opaque mass of matter, deriving most, if not the whole, of her light from the sun; and the phenomena of her phases, of which the explanation already given is thus fully confirmed, are equally decisive as to her roundness. The discoveries of the telescope have still farther extended this analogy, by shewing that the irregular mottled appearance which she presents, even to the naked eye, arises from the extreme diversity of her surface, on which a careful examination discovers what is believed to be great mountains, level plains, and deep vallies. That this is really the case, is concluded from the appearance of dark spots behind the mountains, which, as they vary with the position of the sun, can only be the shadows which they cast behind them on the plains. Before the full moon we see these mountains, forming a very ragged border between its enlightened and dark hemisphere, and projecting their summits beyond the line of light by a quantity which, being measured, indicates their height; according to some astronomers, it surpasses that of any of the mountains on the earth, amounting in many cases to 4 and even 5 miles, while others conceive these estimates to be somewhat exaggerated. The lunar cavities are also indicated by the darkness of the one side, and the brightness of the other, which is opposite the sun; while this contrast vanishes as the moon approaches the opposition where the sun's rays fall directly upon its surface. The depth of these cavities has been estimated at from 2 to 3 miles; they resemble nothing on the earth except it be the bason of our seas. These mountains, cavities, and other irregularities are quite permanent, and preserve always nearly the same position on the moon's surface; its promontories and other remarkable points have been named by some after the most celebrated astronomers—and, by others, after the mountains and countries on the earth.

Atmosphere.—It was long doubted, whether the moon, like the earth, was surrounded by an atmosphere. The fact seems now, however, to be established by the observations of Schroeter. This celebrated astronomer discovered in the moon a faint glimmering light, extending a little beyond the crescent into the dark hemisphere. From the breadth of this line of light, which he ascribes to the twilight produced by the lunar atmosphere, he infers that the height of the denser portions of that atmosphere which reflects the rays of light, and which on the earth rises forty-five miles, cannot be more than 1500 feet; and where it would cease to affect the brightness of a star, not more than 5700 feet. In the observations accordingly, which he made on the stars, scarcely any indistinctness could be observed in them before their disappearing behind the moon. Such being the extreme rarity of its atmosphere, we may conclude that no terrestrial animal could live or respire at the moon, and that its inhabitants, if there be any upon it, must be of a different nature. It is well known, that fluids are more easily dissipated into vapour in proportion as the weight which compresses them is withdrawn. There is reason to think, then, that where so little atmospheric pressure prevails, all must be solid at the surface of the moon. And though its level plains were at one time ascribed to the smooth surface of its seas and lakes, more exact observations render extremely doubtful the existence of any great body of water. The most powerful telescopes rather present the moon to us as an arid mass upon which some have thought they perceived the effects, and even the explosion of volcanoes.

Moon's rotation.—From the motion of the solar spots has been inferred the rotation of the sun on his axis. The same conclusion is drawn, in regard to the moon, from the apparent rest of her spots. For as we go round and round a building when we wish to have a view of it on every side, in the same manner would the moon present to us, in succession, every portion of its surface, if, without moving on its axis, it only revolved round the earth, the appearances being evidently the same as if the earth went round and round the moon at rest. Thus, if a spectator on the earth should observe a remarkable spot S, Pl. 23, Fig. 11. on the centre of the full moon at M, he would evidently lose sight of it by the time the moon, if immoveable on her axis, arrived at her quarter at *m*; and another spot *s*, which he did not at first observe, would now occupy the same centre position; and in order that the same spot as at first should still be observed on her centre, it would be absolutely necessary for her to make a quarter rotation in a direction contrary to that of her revolution. When the moon, therefore, in revolving round the earth, still presents to us a figure whose general appearance, though extremely irregular is always the same, and which must on this account be undoubtedly the same half of her surface, we may be assured that the moon has really a rotation on its axis, in a direction contrary to and keeping exact pace with her revolution round the earth.

Continued observations, however, have discovered some slight motions in the lunar spots; they seem to approach to and recede alternately from the limb; those that are very near the circumference appear and disappear successively on the opposite sides; those on the east appearing while those on the west are disappearing, and conversely; so that the moon herself seems subject to a periodical oscillation on its axis, termed the *libration of the moon*, of which there are three kinds, and all of them apparent and relative to a spectator on the earth. The first is termed the *diurnal libration*,—the second the libration in longitude,—the third the libration in latitude.

Chap. VI. Of the Planets.

The motion of the planets, as we have seen, appears to be extremely irregular, and we have also explained the hypothesis upon which all these irregularities are made to vanish. The indefatigable labours of modern astronomers, aided by the exquisite refinements of science and of art, have confirmed, in a most surprising manner, the truth of this hypothesis, and established upon the evidence of the senses the existence of the beautiful system which Pythagoras had only suspected, on account of its extreme simplicity.

They have also discovered five other bodies, which, as their motions are of the same kind, have been added to the list of the planets. The following are their names :—Juno, Vesta, Ceres, Pallas, and the Georgium Sidus, Herschel, or Uranus. The four first move in orbits, which lie between those of Mars and Jupiter; the last is at the greatest distance of all from the sun; its orbit lies beyond that of Saturn.

By applying the micrometer to measure the apparent diameters of the planets, it is found that their distances from the earth are subject to variations much greater than those either of the sun or moon; and by comparing these distances with their observed right ascensions and declinations we obtain a series of their positions, whose union forms the figures of their orbits. But, on setting down these positions relatively to the earth every day, and joining them together, there arises, for each of the planets a curve, so extremely complex, that the ancient astronomers, neglecting the system of Pythagoras, only wasted their ingenuity in their attempts to reduce them to greater simplicity. Each planet was supposed to move uniformly in a circular orbit, itself in motion on the circumference of another circle, and this again moving round the earth. Each new inequality, however, which observation gradually brought to light in the motions, required the assumption of a new circle or *epicycle*, as it is termed, to represent it; and thus the system, instead of growing in strength and simplicity with the progress of discovery was visibly approaching in complexity that which it attempted to explain. At last the idea was again revived of setting down, not the position of the planets relatively to the earth,—not their *geocentric*, but their *heliocentric* positions;—the positions found by calculation in which they would have appeared to a spectator on the sun.

True orbits of the planets.—The developement of this happy idea has changed the whole aspect of the heavenly motions, and order and consistency have succeeded to the former confusion. It was now found, and the observations of nearly 500 years have only more and more confirmed this result, that a single law, the same which we have already explained for the sun and moon, pervades the whole planetary motions. When their distances from the sun, and their directions are set down for every day, it appears, that while the distances increase, their velocities diminish; so that the radii vectores continually describe areas proportional to the times. In a word, that they all move in ellipses, of which, however various the forms and positions, the sun is the common focus. These ellipses, except in a few cases, differ but little in form from circles; they are all subject to the same kind of changes, both in form and position, and the planets to the same kind of deviations from them with those which have been described in the cases of the sun and moon; the planes of their orbits are all somewhat inclined to that of the ecliptic, though this obliquity never exceeds 7°, except in the case of the new planets between Mars and Jupiter; the point which is termed the apogee in the solar orbit, is termed the *aphelion* in those of the planets; the perigee, the *perihelion*; these points are also termed the *apsides*; and the line which joins them, namely, the greater axis of the ellipse, the *line of the apsides.*

Plate 25. Fig. I. represents the relative dimensions of the orbits of the planets, with the positions of their aphelia and perihelia, their mean distances from the sun in millions of miles being also set down for each. Fig. 2. represents the inclinations of their orbits. Pl. 24. Fig. 5, 6, 7, 8, represents their relative magnitudes, their diameters in English miles being also set down along with the name of each; and the following are the periods of their revolutions; the eccentricities of their orbits, their mean distances being 1; and their mean apparent diameters as seen from the earth:

	Sidereal Revolutions.			Ecc. orbits.	Ap. diam.
	years.	*days.*	*hours.*		
Mercury....	0	87	23	0.205	10″
Venus.......	0	224	16	0.006	58″
Mars........	1	321	23	0.093	27″
Vesta.......	3	240		0.093	0″.5
Juno........	4	131		0.255	3″
Ceres	4	221	12	0.078	4″
Pallas.......	4	221	15	0.245	3″
Jupiter.....	11	317	14	0.048	39″
Saturn......	29	174	1	0.056	18″
Uranus.....	84	29		0.046	4

A very remarkable law, and it is the *third* of the laws of Kepler, connects together these periods with the mean distances of the planets from the sun. It is found, on comparing them together, that *the squares of the periods of the revolutions of the planets are proportional to the cubes of their mean distances.* Thus the period of Jupiter is 4332^d, 14^h, and of Mercury 87^d, 23^h, and the squares of these numbers are nearly as 2425 to 1. Now the mean distances of these planets are expressed by 5.2027 and 0.3871, that of the earth being 1, and the cubes of these numbers are to each other nearly as 2427 to 1.

The new planets between Mars and Jupiter are distinguished from all the rest by their smallness, by the great inclination of some of their orbits to the ecliptic, by their great eccentricity, and, above all, by their orbits crossing each other. These, and other circumstances, which a minute examination of their magnitudes, orbits, &c., has brought to light, lead some to suppose that they are the fragments of a larger planet which once existed between Mars and Jupiter, but which has been burst in pieces by some internal convulsion.

Sect. II. *Nature of the Planets.*

Such are the principal elements of the orbits of the planets. Not content, however, with thus ascertaining, in the completest manner, the laws of their positions; not content with considering the planets merely as luminous objects, astronomers have endeavoured, by means of the telescope, to extend their views into the interior of these apparently impenetrable regions; and the more these researches are continued, the more do these bodies seem to form the parts of a great system,—the more do they resemble each other; and, what is very remarkable, the more do they resemble the earth.

Inferior planets.—Mercury, the nearest of the planets to the sun, is, on that account, in a situation the most unfavourable for observation. Venus, the other inferior planet, is much larger, much nearer to the earth, and much longer visible. On the invention of the telescope, accordingly, very interesting discoveries were made upon her surface. To the naked eye she presents always a full orb, but through the telescope exhibits the same phases with the moon. When first seen in the morning before sunrise, she appears in the form of a slender crescent, with its horns towards the east; her apparent diameter is then also nearly the greatest. In proportion as she advances towards the west, and approaches her greatest elongation, her figure gradually approaches to the form of a semicircle, while her apparent diameter diminishes; she is then evidently receding from the earth. As she returns towards the sun, her figure continues to increase and her diameter to diminish, till the moment of her vanishing in his rays; in a few nights after she is again discovered in the evening, towards the west, with her orb nearly full; but in the middle of this interval she must have been in conjunction with the sun, when her figure, could it have been observed, would have been a complete circle, and her diameter the greatest. Advancing towards the east, her figure diminishes as it had increased, while her increasing diameter indicates her approach towards

The planets. the earth, from which she was before receding. In returning towards the sun, her now semicircular figure is still farther reduced, till she again plunges into the sun's rays, under the form of a crescent, with its horns turned to the west, and in a short time reappears in the morning, in the same form and situation as at first; in the intermediate interval, however, she must have been in conjunction with the sun, when she would have been totally invisible, independent of the brightness of the solar rays; her apparent diameter is then also greatest. As she is then nearest the earth, this is termed her *inferior* conjunction; the opposite one, where she is farthest from the earth, and her figure a complete circle, is termed her *superior* conjunction; it is analogous to the opposition of the moon.

Transits of Venus.—It is in the inferior conjunction, when she is between the sun and earth, that she is sometimes observed like a black spot crossing the disk of the sun. And on the observation of these celebrated *transits* of Venus depend the most accurate method we possess of measuring, by means of the sun's horizontal parallax, his distance from the earth, and from this base the real dimensions of the whole solar system. These phenomena, which are real annular eclipses of the sun by Venus, can only happen, like those of the moon, when the planet is at once in her node and in her conjunction, two conditions which are but rarely found united. The transits accordingly, after succeeding each other in the interval of eight years, do not occur again for more than a century, when they succeed each other again during an interval of eight years; and thus they continue. The last transit happened in 1761; astronomers were sent to different countries to observe it, and it is from these observations that the sun's horizontal parallax has been found.

The phases and transits of Venus prove that she is an opaque globular body, like the sun and moon, deriving her light entirely from the sun. Dark spots, like those of the sun and moon, appear occasionally upon her surface, and a careful observation of them has shewn, 1st, That, like these bodies, she has also a motion of rotation on her axis in a period which is estimated at $23^h\ 21^m$, and on an axis inclined to the plane of the ecliptic; and, 2dly, That immense mountains, of which these spots are the shadows, rise from her surface to the astonishing height, as has been supposed, of 15 or 20 miles. From the appearance also of a faint shade of light along her boundary of light and darkness, similar to our twilight, Schroeter supposes that she is surrounded by an atmosphere, whose density differs but little from that of the earth.

Notwithstanding his proximity to the sun, Mercury has been found, by the help of powerful telescopes, to exhibit the same phases as Venus, to have great mountains on his surface, a motion of rotation in $24^d\ 5^h\ 28^m$, and some have even discovered around him traces of an atmosphere.

Superior planets.—The superior planets appear perfectly round at their oppositions and conjunctions, but in their intermediate positions the figure becomes defective on the side opposite the sun, like the moon in the wane; we hence conclude that they all derive their light from the sun. From the motion of the spots of Mars, Jupiter, and Saturn, the fact of their rotation on their axis has been clearly established: Mars revolves in $24^h\ 39^m\ 22^s$, on an axis inclined $1°51'$ to the plane of his orbit, $59°\ 22'$.; Jupiter in $9^h\ 55^m\ 37^s$, on an axis inclined nearly $90°$ to the plane of his orbit; and Saturn in $10^h\ 16^m\ 2^s$, on an axis inclined about $60°$; and what is very singular, these planets, from the observations of their diameters in different directions, appear to be not perfectly spherical, but, like the earth, flattened, and that to a much greater degree in one direction. In each of them, also, the shortest diameter coincides exactly with its axis of rotation; so that, like the earth, the compression is at their poles, and the protuberance at their equators. Mars and Jupiter seem to be surrounded with atmospheres of considerable density. This is indicated in both by the irregular variations of their spots, arising apparently from the agitation of clouds driven about by the wind, but more particularly on Mars, by the great redness of his light; the density of his atmosphere, according to a principle in optics, obstructing, it is supposed, all but the red rays of the sun. Mars is also distinguished by bright spots, which seem to form a luminous zone or belt round his poles, for they augment and diminish in proportion as they are more or less obliquely exposed to the rays of the sun. They are believed to arise from the reflection of his light from the masses of ice which are supposed to surround the poles of the planet, like those of the earth. Besides his variable spots, Jupiter is surrounded with belts or zones, as in Pl. 24. which, though very variable in their number and magnitude, are nearly always parallel to each other and to his equator. The cause of these appearances is quite unknown. Similar belts are observed on Saturn, but no traces of an atmosphere. Of the other planets, Uranus is too distant, and Vesta, Juno, Ceres, and Pallas, too small, to admit of any observation from which either a revolution on an axis, or the contrary, can be inferred.

Secondary planets.—But the most remarkable of all the modern discoveries concerning the planets, is the existence of certain small stars, which continually accompany some of them in their course round the sun, and which have been hence termed their Satellites. Four of these stars are always seen along with Jupiter, and they are easily observed to be continually in motion relatively to the planet. They remain always nearly in a straight line, parallel almost to the plane of the ecliptic; but each night they are ranged upon it in a different order. By comparing their successive positions, it appears that these alternations occur according to a certain law. Each satellite, after advancing a certain distance towards the west of the planet, returns towards it, passes to the opposite side, and after receding to the same distance as before, again returns, overtakes the planet, again advances towards the west, and thus continues to exhibit a perpetual series of oscillations. That satellite which recedes least from the planet is termed the first, the next the second, and so on in the order of their greatest distances. It is natural to think, however, that these oscillations, like those of Mercury and Venus about the sun, are only apparent, and that the satellites really circulate round their

Of comets.

planet, as the moon circulates round the earth. This singular result is confirmed by what happens in the middle of their apparent oscillations. Sometimes, when any of the satellites passes from the eastern to the western side of the planet, it is observed like a spot upon the disk of Jupiter. Another dark spot is also seen accompanying it. In passing again from the western to the eastern side of the planet, the satellites suddenly disappear entirely from our view, and in a short time reappear a little farther toward the east. It was soon conjectured that these disappearances like those of our moon, in opposition, were real eclipses of the satellites; as in passing beyond the planet they entered into its shadow; and that the dark spot that was seen traversing along with them the disk of the planet, was nothing else than the shadow which the satellites projected behind them in passing between the sun and the planet. The observations of one hundred years have fully verified these conclusions, and led to a complete knowledge of the motions of the satellites. The first satellite revolves in $1^d\ 18^h\ 27^m\ 33^s$; the second in $3^d\ 13^h\ 13^m\ 42^s$; the third in $7^d\ 3^h\ 42^m\ 33^s$; and the fourth in $16^d\ 16^h\ 32^m\ 8^s$; and the distance of each satellite, the radius of Jupiter being one, is, 1st, 5.70.; 2d, 9.06.; 3d, 14.46.; 4th, 25.43. In their revolutions round the planet, the satellites are found to obey the same law which governs the planet in its revolution round the sun. Their radii vectores describe round the planet areas proportional to the times. The orbit of the fourth is sensibly elliptical; those of the three first circular; and in all of them the squares of the periods of their revolutions are proportional to the cubes of their mean distances from the planet. From this striking analogy these bodies have been termed *secondary* planets; those round which they revolve being distinguished by the title of *primary*. These secondary planets are very analogous to our moon; like her they enlighten the primary planet in the absence of the sun, and revolve round it according to the same law by which she revolves round the earth. Like the moon, also, they are occasionally eclipsed by the planet. From observations on their surface, the curious fact has also been established, that, like the moon, they have a rotation on their axis, each in the exact period of its revolution round the planet.

The eclipses of Jupiter's satellites, as they happen very frequently, and at the same instant all over the earth, have therefore been employed to great advantage in finding the longitude of places. The tables of their motions have, on this account, been brought to great perfection. The instant, on the meridian of Greenwich, each satellite enters or quits the shadow of Jupiter,—the instant of its *immersion* or *emersion*, as they are termed, is there set down; and by observing the instant at any other place, the difference of time gives the difference of longitude. At sea these observations are impracticable, on account of the unsteadiness of the vessel.

No fewer than seven satellites have been discovered round Saturn, and six round Uranus; as far as they have been observed, they are subject to the same laws as those of Jupiter.

Saturn's ring.—Besides these appearances, which resemble those of the other planets, Saturn presents one, as at Plate 24. Fig. 10. which is quite *unique:* he is surrounded by a broad, thin ring, concentric with himself, and separated from him on all sides by a distance equal to his diameter. This ring has the appearance of an ellipse, of which the form is continually changing. The breadth is observed gradually to diminish; the whole ring disappears and reappears in a short time, when the breadth begins to increase, and continues for a certain period, and then diminishes as at first. By comparing these variations with the positions of Saturn and the Earth, it has been found that the ring is circular, as at Fig. 11. but appears under the form of an ellipse, on account of being more or less obliquely exposed to our view by the revolution of the planet. From the appearance of one or more dark lines along the middle of the ring, and concentric with it, the ring is supposed to consist of two or more rings, quite detached from each other. The following are the dimensions of these rings:

	Miles.
Inside diameter of the interior ring,	146,000
Outside diameter of the interior ring,	184,000
Inside diameter of the exterior ring,	190,000
Outside diameter of the exterior ring,	205,000

The plane of the ring coincides with the plane of the equator of Saturn; and Dr Herschel has discovered that it revolves in this plane on an axis perpendicular to it, and passing through the centre of the ring. The period of this rotation is the same with that of the planet, namely, a little more than ten hours.

The nature and uses of these singular bands are quite unknown; but as the ring disappears when unenlighted by the sun, and when enlightened casts a deep shadow upon the planet, it is concluded that both the ring and the planet are opake bodies, deriving all their light from the sun.

Chap. VI. On Comets.

All the observations that have been made upon the fixed stars concur in placing them, as we have already supposed, at a distance immense in relation to the dimensions of the solar system. Their parallax is totally insensible. The telescope, also, which enlarges the disks of the sun and of the most distant of the planets, has no magnifying effect whatever upon any of the fixed stars, even though we employ the most powerful instruments that have ever been constructed; though we thus discover an innumerable multitude of new bodies, termed *telescopic stars*, which are subject to the same common motion with the rest, and of which the number always increases in proportion as we increase the power of the telescope,—yet as the glare of light with which they are surrounded is thus taken away, the stars seem rather to suffer by this application; and though our telescopes magnify 200 or 300 times,—though the effect therefore is the same as if these bodies were brought 200 or 300 times nearer, as they still shine like brilliant points in the sky, it is impossible, at such immense distances, and with diameters so insensible, that they could be visible to us if they were only enlightened by the sun. It is more natural to think they are like the

Motion of the earth.

Sun, great masses of matter shining with their own light. Another set of bodies, of a different nature, and which we have not hitherto noticed, appear occasionally in the heavens. When first observed they are very small, their light is very faint, and they move very slowly among the stars; by degrees, they increase in brightness and velocity, and after a certain period diminish in the same manner, and at last disappear. Being usually accompanied with a sort of *tail* or *coma*, they have been called *comets*. In ignorant ages they were regarded with terror; but their motions are now followed with interest and curiosity. When observed through a telescope, they seem a mass of vapours, at the centre of which is commonly a nucleus, more or less opake; but some of them have appeared without any sensible nucleus, the stars, it is said, having even been observed through them.

It was long doubted if comets were real stars; they were looked upon as simple meteors, engendered in the air by the influence of certain vapours. All the comets, however, that have been observed, have little or no parallax, which shews that they are far beyond the limits of our atmosphere. Besides, their apparent motions across the stars appear subject to regular laws, by which even their return can be sometimes predicted. It is natural to conclude, that the comets are permanent stars, like the planets, but subject to a different course. From the observations that have been made upon those that have successively re-appeared, it is probable that they move in very eccentric ellipses, approaching much nearer the sun in one part of their course, and receding to a much greater distance in another, than any of the planets. Hence arise those progressive variations which we observe in their brightness, according to their distance from the sun; the latter either inflaming or only enlightening them. As the tail increases as they approach, and diminishes as they recede from the sun, it is probably only an enormous mass of vapours, which the intense heat of the sun raises up. Its length and form are very various; sometimes it is only a few degrees, at others it is more than a quadrant. In the great comet which appeared in 1680, the tail subtended an angle of 70°,—in that of 1618 an angle of 104°.

Chap. VII. Of the Motion of the Earth.

Having in the preceding chapters given an account of the discoveries which astronomers have made concerning the heavenly bodies, it only remains to point out the conclusions to which they necessarily lead. We shall first consider the motion of the earth.

Sect. I. *Of the Diurnal Motion.*

We have already shewn that the phenomena of the diurnal motion, to which all the heavenly bodies are subject, are exactly the same, whether we consider them all carried round the earth, supposed immoveable, or the earth itself to revolve in a contrary direction; we have also endeavoured to obviate the objections to this latter hypothesis which naturally arise in the mind, and to shew that it is even much more natural to admit the motion of the earth, and to regard that of the heavens as only apparent.

Motion of the earth.

The above discoveries confirm this result in a remarkable manner; for we are now certain, *first*, That the heavenly bodies are placed at very different distances from the earth, the sun and the stars being much farther from it than the moon; that the planets move round the sun at different distances, and in different periods; and the comets also in every direction. These circumstances render certain the fact of the insulation of these bodies in respect to each other, and thus strengthen the argument which is drawn from the difficulty of conceiving so many of them, unconnected with each other, impressed at the same time with a common motion.

2dly, The earth is a globe whose radius is not above 8000 miles; the sun, as we have seen, is incomparably greater; if his centre be supposed to coincide with that of the earth, his volume would include the lunar orbit, and extend as far beyond it; if his magnitude were exhibited upon the same scale with those of the planets in Plate 24. his diameter would be two feet. Is it not infinitely more simple to suppose in our little globe a motion of rotation, in which there is nothing contrary to nature, than to imagine the immense mass of the sun to describe every day round us a circumference of many millions of miles, and with a velocity of nearly 200,000 miles in a minute: What power is there in the earth which could balance the tremendous centrifugal force, that would be generated by so rapid a revolution of so great a body? what prodigious force would be necessary to prevent its flying from its centre of motion, like the stone from the sling?

But this is not all; the same difficulties arise in regard to the planets. In Pl. 24. Fig. 6—9. is exhibited their relative magnitudes, and in Pl. 25. their distances from the sun, or their mean distances from the earth. A better idea of these distances may perhaps be formed from the following consideration: Suppose a cannon ball to fly with a velocity of 480 miles an hour,—projected from the sun, it would move onwards for seven years without reaching the orbit of Mercury, the nearest of the planets to the sun,—in seven months more it would arrive at this orbit,—at that of Venus only in fourteen years,—of the earth in nineteen years three months,—of Mars in twenty-nine years two months,—of Jupiter in 100 years, of Saturn in 184 years, and at that of Uranus in 350 years. We must, upon the above hypothesis, suppose the same diurnal motions in all these bodies, and also in the comets and satellites motions exactly proportioned to their distances. Nay, what is much more than all this, we must extend them to that multitude of stars with which the heavens are covered; and all these bodies, whose distance it is impossible to conceive, would turn together every day round an imperceptible point with perfect regularity, and with a velocity that frightens the imagination.

3dly, We have seen that the whole heavenly bodies seem to have another common motion much slower, and in the opposite direction to that of the diurnal, and which, if the earth be immoveable, can only be represented by supposing the celestial sphere in motion round the axis of the ecliptic. Thus, the whole system, composed of so many bodies, differing from each other so much in their magnitudes, mo-

Motion of the earth.

tions, and distances, would be again subject to a general motion, which disappears, if we suppose the terrestrial axis to move round the axis of the ecliptic.

4thly, These arguments are strengthened from analogy, by the discovery of a rotatory motion in all the planets whose surfaces have been sufficiently observed, and in all of them, from west to east, the direction of that which the diurnal motion of the heavens would indicate to the earth,—Jupiter greatly exceeding the earth in magnitude, moves round its axis in less than twelve hours. An observer on its surface would see the heavens revolve round him in that time; yet that motion would only be apparent. Is it not, therefore, reasonable to think, that it is the same with that which we observe on the earth? What confirms in a very striking manner this analogy is, that both the earth and Jupiter, as well as some of the other planets whose rotations have been observed, are flattened at the poles. Though we are ignorant of the exact process by which this figure has been brought about, yet it can hardly be doubted that, in the planets, it is the effect of the centrifugal force. Conversely, therefore, this figure of the earth is almost a direct proof of the operation of a centrifugal force, produced by the earth's rotation. This force should likewise diminish the force of gravity at the equator; and that this diminution does take place, is proved by experiments which have been made on the lengths of pendulums.

Every thing, then, leads us to conclude, *that the earth has really a motion of rotation*, and that the diurnal motion of the heavens is merely an illusion which is produced by it.

Sect. II. *Annual Motion.*

The annual motion of the earth is indicated by proofs as strong and as numerous. In the *first* place, the planets resemble the earth in almost every particular. Like the earth, they are opaque bodies, deriving all their light from the sun. Like the earth, many of them have moons circulating round them; and, like our moon, turning also each of them round its axis in the exact period of its revolution round the planet. The planets also are almost all surrounded with atmospheres; their surfaces are mountainous and irregular, but, upon the whole, globular; and in every instance where the effect is not too minute for our observation, they are, like the earth, flattened at the poles, and bulging out at the equator. There is hardly a case, therefore, where we would say with more propriety that they are all of the same *class*, and thus add the earth to the list of planets. But it is the distinguishing mark of a planet to move round the sun in an elliptic orbit, differing but little from a circle, and at the same time, in every instance where the fact can be ascertained, to turn on its own axis. We are now certain that this latter motion belongs to the earth; and as we have seen that the appearances are exactly the same as if the earth also turned round the sun in an ellipse, this second motion almost follows as a matter of course. But there is still another very remarkable circumstance in which the earth resembles the planets. We have seen that an invariable law connects together their distances from the sun, and the periods of their revolutions; but this law extends to the earth, if we consider it as a planet; for if the proportion be stated,—as the cube of the mean distance of Mercury, 0.387, is to the cube of the earth's mean distance, 1, so is the period of Mercury to a fourth proportional,—this fourth term will be found equal to $365\frac{1}{4}$ days, the exact period of a sidereal year, the time which the sun's motion would indicate for the length of the earth's period, if that motion be ascribed to the earth. The very same quantity results as the fourth term, if the proportion be stated with the distance and period of Venus, of Mars, or any other of the planets; and as it is impossible, where so many numbers are concerned, that this singular coincidence could be the effect of chance, taken along with the above resemblances it amounts almost to a direct proof of the annual motion of the earth.

2dly, If, led away by appearances, we suppose the sun really in motion round the earth, we must also suppose, in order to explain their stations and retrogradations, a similar motion in all the planets. As the planets Jupiter and Saturn move round the sun, and carry all their satellites along with them, we must suppose that the sun, in his motion round the earth, carries in the same manner all the planets, as well as their satellites, along with him. But these various notions are of the same kind with those which the diurnal motion presents, and which, we have seen, are quite illusory. Besides, it seems to be a general law, that the smallest bodies of the solar system turn round the greater. The moon is 49 times smaller than the earth, round which it revolves. The planets Jupiter and Saturn are each of them larger than any of their satellites, or all of them put together; and the whole of the planets and satellites together are nothing equal in magnitude to the sun, the common centre of all their motions. How improbable is it, therefore, that the order of nature should be reversed in the case of the earth, in physical qualities so inferior to Saturn, to Jupiter, or to Uranus. Thus, in every view, the above supposition is inadmissible, and we are again brought back to the motion of the earth as the only solution of all the difficulties. *Lastly*, a direct proof of the annual motion of the earth is obtained from the phenomenon termed the *aberration of light*, or *the aberration of the fixed stars*. This is a very slight motion to which the stars are subject, and which is explained most satisfactorily, and in its minutest details, by ascribing it to the motion of light combining itself with the motion of a spectator on the earth, and thus producing in the stars a slight deviation from their true places, but which is quite inexplicable on any other hypothesis.

Collecting all these evidences, then, and considering also that there is no appearance inconsistent with it; and that there is not in nature any other way in which it could have been indicated, it may be reckoned as a fact beyond all question, *that the earth has really in space a motion of revolution round the sun, as well as of rotation on its axis.*

Gravitation.

Chap. VIII. Of the Principle of Universal Gravitation.

Thus the observations of modern times have completely verified the beautiful theory which we noticed at the conclusion of Part I. But when we consider a system composed of so many bodies turning round a great centre of heat and light, themselves also the moveable centres of the perpetual revolutions of inferior systems; when we consider, too, that these bodies, however various their distances from the centre, and the periods of their revolutions, are all governed in their motions by the very same laws—it is impossible not to recognise the operation of some more general cause which actuates the whole.

Can these bodies, then, though separated by distances so immense, still have any effect upon each other? Let us consider what happens on our own planet. There is no power on the earth whose operation is so constant and so universal as that of gravity. It is felt on the highest mountains and in the deepest cavities, and, whatever be its nature, its effect invariably is, when nothing opposes it, to make all bodies descend in straight lines directed towards the centre of the earth. It is thus that the rain is precipitated from our atmosphere, carried through all the windings of our rivers, and finally deposited in the ocean, where it is no sooner raised up by the opposite force of evaporation, than it is again precipitated by the effect of this ever-working and all-powerful agent. The most familiar fact in nature, therefore, is that of one mass of matter acting with great intensity upon another at a distance; and this force, if its influence could be supposed to extend to the moon, and also to exist on the planets, and even on the sun, extending from the former to their satellites, and from the latter to the remotest extremities of the system, seems admirably calculated for drawing these bodies each to the centre of its motion. If a force of this kind, however, operated alone, their motions, like the fall of a stone, would soon terminate by their arrival at their centres of attraction; but we often observe on the earth the power of gravity combined with other forces, so that there arise from their joint influence motions very varied, and, in some cases, like those of the planets, perpetual. Thus the rain, precipitated by the force of gravity, and carried into the sea, is raised up by the force of evaporation; and, being transported by the winds, it is again precipitated in the same place, and is thus made, by the combined effect of these forces, to describe a species of re-entering curve. Thus a balloon, instead of descending, remains sometimes suspended, and sometimes ascends with great rapidity. Thus, also, a body projected from the hand, or from a cannon, rises into the air, and then descends, describing a curve line, which has been found, both by theory and experiment, to be one of the conic sections termed *the parabola*. May not then the force of gravity be so combined with some other as to make the planets describe another of the conic sections, namely, *the ellipse?* The possibility of this combination is made evident by a very simple experiment. Suspend a ball by a long thread directly over, and at the same height with a candle or other object,—if the ball be withdrawn to some distance from the candle, the centre of its attraction, it will, when left to itself, descend directly towards the candle, and, if the candle were removed, would continue for a long time to oscillate backwards and forwards; but withdraw the ball to the same distance again, and project it in a direction at right angles to that in which it would oscillate by the combined effect of the two forces of projection on the one hand, and gravity towards the centre, on the other, it will then describe round the candle circles or ellipses of various magnitudes and eccentricities, according to the force of projection. As it continues, however, to revolve, it will gradually diminish in velocity, approach to and finally settle in the centre of attraction; but as the force of gravity never diminishes, this retardation must arise from the resistance of the air and the friction of the materials, and if these obstacles were removed, it is certain, from the principles of mechanics, that the body would continue for ever to revolve round the candle in a manner somewhat similar to the revolution of a planet round the sun.

To verify the supposition of the planets, comets, and satellites being actuated by similar forces, astronomers have considered them as all gravitating bodies, which have been launched into space, at a certain distance from a point to which they have been at the same time endowed with a tendency to approach. They have then decomposed their motions, and valued separately the effects of the impulse which makes them circulate, and that of the force which retains them in their orbit. From the laws of Kepler, which are established by observation, they have concluded, by a rigorous calculation, aided by a refined analysis, *first,* That the force which solicits the planets is directed towards the centre of the sun; this is derived from the law, that the areas described by the radius vector of every planet are proportional to the times: *Second,* That the force which animates the planets and comets is in the inverse ratio of the squares of their distances from the sun; this is derived from the second law, that the orbits of the planets and comets are conic sections, of which the sun occupies one of the foci: *Third,* That it is the same force which animates all the planets and comets; this is derived from the third law, which connects the distances of the planets and comets with the periods of their revolutions.

In this manner the observations of Kepler lead directly to the knowledge of the general force which actuates the bodies of the solar system, and which has been called *solar attraction.*

The motions of the satellites presenting similar phenomena, and being equally subject to the laws of Kepler, it results from them that every system of satellites is attracted towards its planet by a force reciprocally as the squares of their distances, and therefore similar to the solar attraction.

It has also been established, by the comparison of the celestial phenomena, that all the particles of matter have a mutual attraction for each other, in the direct ratio of their masses, and the inverse ratio of the squares of their distances. This great and simple law of nature, which finely harmonizes the hea-

Gravitation.

venly motions, was discovered by Newton. It is termed the principle of *universal gravitation.*

But it will receive additional confirmation if all the celestial phenomena can be deduced from it as necessary consequences; and this is the case in a most remarkable manner. In thus following out the principle in all its details, the greatest difficulties have been experienced. Observations, in many instances at variance with theory, could not be reconciled with it, though all the circumstances of each case were weighed with the utmost attention; doubts were raised as to the efficacy of the principle of gravitation, and the agency of other forces was introduced for the purpose of explaining the appearances; but at last it was discovered that the calculations had not been rigorously exact, and finally the whole of those discrepancies yielded to the repeated attacks of a more improved analysis. "Such," says La Place, alluding to the principle of gravitation, "has been the fate of this brilliant discovery, that every difficulty that has arisen has only furnished for it, a new subject of triumph; and this is the most indubitable characteristic of the true system of nature."

Disturbing forces.—Since the principle of attraction is universal throughout the system, the planets and satellites, while they are attracted each to its centre of revolution, must at the same time attract each other; and from these *disturbing* forces, as they are termed, arises the deviation of the planets and satellites from the true elliptic motion, as well as those secular inequalities of which observation has only indicated the existence, but could not have developed the laws. Hence also is deduced one of the most important conclusions in Astronomy, namely, the stability of the system.

When it was discovered that the orbits of the planets were subject to a perpetual change, that the solar ellipse was gradually approaching to the form of a circle, and its plane to the plane of the equator, it was thought that the system contained within itself a principle of dissolution, and, for its perpetual existence, would require occasional retouches from the hand of its great author. It now appears, however, that all these changes are oscillatory,—that after proceeding for certain periods in one direction, they return in the opposite,—and after continuing in it for the same periods, again proceed as at first. Though the system, therefore, is subject to a perpetual change, its mean state is that of a perpetual equilibrium; from this it no sooner deviates to a certain extent, than the error, by an admirable provision, corrects itself, and the system is brought back to its mean state; but the impulse thus given carries it a little farther, the error is again corrected, and the system again returns to the point, about which it will certainly thus continue for ever to oscillate, unless it be disturbed by some external violence.

The precession of the equinoxes is fully accounted for by the principle of universal gravitation; it is found to arise from a real conical motion of the earth's axis, produced by the action of the sun and moon upon the bulging mass of matter accumulated at the equator.

The singular law by which the whole of the satellites turn on their axis, in the exact period of their revolution round their planets, so as continually to present to them the same face, is another consequence of the same principle; and on it also the phenomena of the tides in all their details are dependent. In short, there is no appearance in the whole system of the sun, the planets, and the satellites, which is not completely accounted for by this great law of nature, and deduced from it with admirable precision.

"The motion of the earth," says La Place, "which had obtained the assent of astronomers, from the simplicity with which it explained the celestial phenomena, has received, from the principle of gravitation, a new confirmation, which has carried it to the highest degree of evidence of which physical science is susceptible." After shewing that this hypothesis reduces to the least possible the number of assumptions on which it is built, by only supposing the planets to have received a single impulse in a direction not passing through their centres of gravity, he proceeds: "This principle has, besides, the advantage of connecting this theory with all the celestial phenomena. Without it, the ellipticity of the planetary orbits, the laws which the planets and comets follow in their revolutions round the sun, their secular and periodic inequalities, the numberless inequalities of the moon, and of the satellites of Jupiter, the precession of the equinoxes, the rotation of the terrestrial axis, and, lastly, the ebbing and flowing of the sea, would only be insulated and unconnected phenomena. It is really a circumstance deserving our admiration, the manner in which all these phenomena, at first sight so unconnected, flow from one law which connects them with the motion of the earth; so that this motion once admitted, we are conducted by a series of geometrical reasoning to these phenomena. Each of them furnishes, therefore, a proof of its existence; and if we consider that there does not exist a single phenomenon which cannot be referred to the law of gravity, and that this law determines with the greatest exactness the positions and motions of the heavenly bodies through the whole of their course, there will be no reason to fear that its truth will be questioned in consequence of any phenomena hitherto unobserved. And, finally, when we see that Uranus and its satellites, lately discovered, obey and confirm the same law, it is impossible to refuse assent to these proofs, and not to allow that nothing in natural philosophy is more completely demonstrated than the motion of the earth and the principle of universal gravitation, in proportion to the masses, and inversely as the squares of the distances."

Having thus ascended to the first cause of the phenomena, astronomers have, by descending to its effects, discovered many things which observation alone could not have indicated. In this manner they have deduced what seems at first so utterly beyond the reach of human knowledge, the masses and densities of the planets. If the quantity of matter in the earth be denoted by 1, the mass of the sun is found to be 334,000, and of the planets Mercury 0.165, Venus 0.89, the Moon 0.025, Mars 0.087, Jupiter 312.1, Saturn 97.70, Uranus 16.80; and if the density of water be 1, that of the sun is $1\frac{2}{15}$; Mercury $9\frac{1}{6}$, Venus $5\frac{3}{4}$, the Earth $4\frac{1}{3}$, the Moon $5\frac{1}{2}$, Mars $3\frac{2}{7}$, Jupiter $1\frac{1}{23}$, Saturn $0\frac{11}{34}$, Uranus $0\frac{99}{100}$. Hence also they have deduced the laws of those inequalities in the motions of the planets which only recur after the lapse of ages, and have thus been enabled to give to astronomical tables a degree of precision almost equal to observation, and to tell in this manner the *state of the heavens*, both in the ages that are past and in those that are to come. Astronomers have thus, in the words of Biot, "decomposed the system of the world, reduced it to its single element, and recomposed it again." In this view, astronomy is the noblest monument of human genius, and the system which it discloses, bearing evident marks of wisdom and design, must be the work of infinite intelligence and almighty power.

Chap. IX. Of the Fixed Stars.

Let us now extend our view to the region of the fixed stars, from which every thing thus leads us to detach the system of the sun and planets, to which we ourselves belong.

Immense distance.—We have already seen, that, to measure the distance of an inaccessible object, it is necessary to transport our instruments to different positions, and that any base that we can obtain on the earth is too small to determine with accuracy the distance of the sun; this method is still more imperfect in regard to the more distant planets and the comets; while it fails altogether in the case of the fixed stars. As we are now certain, however, that the earth, (Pl. 23. Fig. 10.) moves round the sun, S, at a mean distance of 95 millions of miles, it is equally certain, that every six months we are transported, along with our instruments, from E to F′, over double this space; so that were the distances of the stars within the bounds of our conception, it would certainly be indicated by this great change in our position. But though we are thus carried twice every year from the one extremity to the other of a base of 190 millions of miles, over a space which a cannon ball would hardly describe in 40 years, and from the one end of which its report would only be heard at the other after an interval of more than 25 years; and though the precision of modern instruments is such, that the angle E S′, (which is termed the *annual* parallax of the stars,) would certainly be perceived, though it amounted but to the half-millionth part of the circumference, yet astronomers have never been able to detect, from this ample base, the slightest change in the position of any of the stars; we conclude, therefore, that their distance from the earth bears no sort of proportion even to the diameter of the earth's orbit, or, at any rate, that they are at least 100,000 times farther off than the sun. Thus these bodies seem to recede the farther, the nearer we approach to a knowledge of their real situation.

Supposed to be suns.—Since, at this enormous distance, the stars, whose diameters are insensible, still shine with such lustre, it is impossible to doubt that they are luminous of themselves, and that they are so many suns spread though the regions of space.

It is natural also to think that they do not exist there for nothing, but rather that they are intended to give light and heat each to a system of planets circulating round them.

Subject to changes.—The stars must undergo great changes, since they are sensible at so great a distance. Many of them are subject to periodical variations in brightness; some new stars have appeared; and some which were once observed have disappeared entirely from the heavens; some also have appeared for a short time, and, after increasing in brightness, have diminished in the same manner, and finally disappeared. Such was the star that appeared in 1572 in the constellation of Cassiopeia. It became suddenly so conspicuous as to exceed the brightness of Venus or Jupiter, and could be seen at mid-day in the meridian; by degrees it diminished, and finally disappeared six months after its first appearance, without changing its place. Its colour in these intervals underwent great variation; it appeared at first of a bright white, like Venus; then reddish, like Mars, and lastly, of a white lead colour like Saturn. These appearances seem to indicate great conflagrations upon these bodies.

Seem to be in motion.—Though the stars appear to us in repose relatively to each other, they may not be so in reality; for, on account of their great distance, they might move through spaces of inconceivable extent, without our perceiving it, even with the finest instruments. In fact, a slow motion has been observed in some of them, which is represented by supposing the sun himself, along with all the planets, in motion toward the constellation Hercules. It is probable, therefore, that these systems of suns and planets move round each other in the same manner as the planets round their suns, and the satellites again round their planets.

At different distances.—It is impossible to believe that these suns or stars are all at the same distance from the earth; it is more natural to think that those which are largest and brightest are the nearest, and that those of inferior magnitudes are proportionally farther off. What are we to think, then, of the distances of those stars which are invisible to the naked eye, but appear in great numbers through a telescope; and, again, of those which are only visible with telescopes of the most powerful kind? Light moves with inconceivable rapidity, reaching us from the sun in eight minutes; it is not unreasonable to suppose that these stars may be so far distant that light would take many years in travelling from them to the earth, and not impossible that there may be some of them whose light has not yet reached us, and that the light of others which may have long since ceased to exist still shines on the earth.

Nebulæ.—Even to the naked eye the stars do not seem uniformly scattered over the heavens, but are arranged in groups, and in many cases massed together, so as to have the appearance of a *nebula*, or cloud of light. The same thing is observed through the telescope; innumerable multitudes of stars, formerly invisible, are now distinctly perceived; what appeared to be nebulæ, now seem an innumerable collection of distinct stars, and of other nebulæ, of which the distinct stars are again observed by more powerful instruments, as well as another set of nebulæ still; vast collections of nebulæ also are discovered which are invisible to the naked eye. These nebulæ are sup-

Fixed stars. posed by astronomers to be collections of suns, revolving, perhaps, round each other in the same manner as the suns of which they are composed, each carrying along with it its system of planets and satellites. That large zone of light, which stretches across the heavens, and is termed the *milky way*, is supposed to be a nebula of this kind, to which our sun and planets belong, and which appears to us so large on account of our proximity to it. Its light is owing to the immense multitude of stars of which it is composed; within a portion of it, 15° long and 2° broad, Dr Herschel counted no less than 50,000, and suspected that there were as many more, which, from the want of light in the telescope, he only observed now and then.

Since the number, then, of the stars in the nebula which is nearest us is so incalculable, and their distances so great, that we are certain a cannon ball, travelling at the rate of 400 miles an hour, would not reach even the nearest of them in two millions of years, what can we think of the number and distances of the stars in those multitudes of nebulæ which appear, even in the finest telescopes, only as masses of light! The imagination is lost in contemplating these extremes of extent; and the more we reflect, the more impossible is it to fix, or even to conceive, bounds to the universe.

Whether or not the stars be suns, each enlightening its system of planets and satellites, it is surely very probable that the planets of our own system are inhabited by animated beings;—for as it is certain that the sun imparts both light and heat to the planets as well as to the earth, and as his influence gives birth to the animals and plants which cover the earth, "analogy," as La Place observes, "induces us to believe that it produces similar effects on the planets; for it is not natural to suppose that matter, of which we see the fecundity develope itself in such various ways, should be sterile upon a planet so large as Jupiter, which, like the earth, has its days, its nights, and its years, and on which observation discovers changes that indicate very active forces. Man, formed for the temperature which he enjoys upon the earth, could not, according to all appearance, live upon the other planets; but ought there not to be a diversity of organization suited to the various temperatures of the globes of this universe? If the difference of elements and climates cause such variety in the productions of the earth, how infinitely diversified must be the productions of the planets and their satellites. The most active imagination cannot form any just idea of them; but still their existence is extremely probable.

Explanation of Plates.

Plates 21. 22. and 23. Fig. 1—11. illustrate the appearances and motions of the Heavenly Bodies, and are sufficiently explained in the different parts of the treatise from which the references are made.

Plate 23. Fig. 12. is the representation of an ingenious Apparatus, contrived by Mr Kerr, optician in Edinburgh, for the purpose of exhibiting a popular view of the motions of the planetary bodies round the sun. A is the sun; B, mercury; C, Venus; D, the earth, with the moon; E, Mars; F, Jupiter, with his four satellites; G, Saturn, with his satellites; and H, Uranus, or the Georgium Sidus, with his satellites. Fig. 12. is a front view of the apparatus. Fig. 13. is a side view, and will afford a distinct notion of its construction. I K is a pillar which supports the whole apparatus. Each of the planets, which have the same letters of reference as in Fig. 12. is attached by an arm to the axis L, which is turned by the winch M; but the immediate connexion is by a small arm which moves on the extremity of the larger arm, projecting at a right angle. When the axis is turned round, the planet by its weight is always in a perpendicular position, and in this way describes an elliptic figure, which is its true orbit. The moon attached to the earth, and the satellites of the other planets being connected with their centres of motion, in the same way, perform similar revolutions in similar orbits.

Plates. Fig. 14. is an Apparatus invented on the same principle, by the same ingenious artist, for illustrating the change of seasons. A is the sun; B B B B is the earth in different positions of its orbit; and N S is the north and south. C D is an arm which is turned on an axis; and to the extremity of this axis the earth, B, is hung by a shorter arm, so that when the axis to which the longer arm is attached is moved round, the ball representing the earth is always suspended in a perpendicular position; and from the inspection of the different positions of the earth expressed by the dotted lines, it will appear that different parts of it are illuminated and heated at different periods of its annual revolution, thus producing the diversity of seasons. The dotted line, E F G, marks the elliptical orbit of the earth.

Plate 24. Fig. 1. exhibits a view of the Phases of the Moon, or her appearances in different positions in her revolution round the earth, from new to full moon. Fig. 2. represents the appearances of the moon in a contrary order, or from the full to the change. Fig. 3. represents the appearances of the sun in eclipses. Fig. 4. is an annular eclipse, in which a rim of light surrounds the dark body.

Fig. 5. is a view of the Moon in her mean libration, according to the observations of Riccioli and other astronomers. Fig. 6. 7. 8. 9. represent the relative magnitudes of the planets, with the diameters of each in English miles. Fig. 10. a view of Saturn, his belts, and ring, as seen from the earth. In this oblique view the ring appears elliptical; but when seen above the plane of his orbit, as at Fig. 11. it is circular. Fig. 12. a Comet.

Plate 25. Fig 1. is a representation of the relative dimensions of the Orbits of the Planets, the positions of their aphelia and perihelia, and their mean distances from the sun in millions of miles. Fig. 2. exhibits the inclinations of their orbits.

ASTRUC, John, an eminent French physician, was born at Sauve in Languedoc, in 1684, was educated at the university of Montpellier, and having passed through some inferior degrees, was created, in 1703, doctor of medicine. He was first known to the public in a controversy on the subject of digestion, in which he maintained, that this process depended on a peculiar fermentation, in opposition to the doctrine of trituration, or mechanical action, which was held by other physiologists. In 1710 he was appointed professor of anatomy and medicine at Thoulouse; and in 1717 he succeeded to the medical chair at Montpellier, and acquired great reputation by his lectures. The fame of Astruc procured for him an invitation from the king of Poland to become his physician; but after a short abode with that monarch, he returned to France, fixed his final residence at Paris, was appointed physician to the king, and preferred to the professorship of medicine in the Royal College. In this conspicuous station, his talents, learning, and medical skill, found ample scope; and the celebrity of his lectures attracted crowds of students, foreigners as well as natives, from all quarters. Astruc was the author of numerous works, chiefly connected with medical subjects; his Treatise on Female Diseases still retains considerable reputation; and, at the venerable age of 82, he closed, in 1766, an active, honourable, and useful life.

ASTURIAS, two provinces of Spain, formerly distinguished by the names of Asturia of Oviedo, and Asturia of Santillana, but now united into a principality, from which the eldest son of the king derives the title of Prince of Asturias. The bay of Biscay on the north, Gallicia on the west, and the kingdoms of Leon and Castile on the south and east, form the boundaries of the principality, which includes at least 700 square leagues of the most mountainous district of Spain.

Calcareous rocks, as secondary limestones, full of animal remains, some of which are excellent marbles, chalk, marl, and gypsum, are the prevailing strata in many regions of the Asturias. Some indications of coal have been observed; and ores of copper, iron, lead, and cobalt, have been wrought, but to a limited extent. Many districts are covered with thick and extensive forests of valuable timber trees. The climate is moist, and heavy rains are frequent.

The population of the Asturias is estimated at 350,000. The ancient inhabitants presented a most formidable opposition to the Romans; and while the rest of Spain was held in subjugation by the Moors, their bravery and perseverance enabled them to preserve their independence, contributed to the final expulsion of the invaders, and procured from their grateful countrymen the honourable appellation of *illustrious mountaineers*. The present race is characterized by simplicity of manners and probity of life. The labours of husbandry are chiefly confined to pasturage. Large herds of cattle, and numerous flocks of sheep, are reared in the mountainous districts; but in less elevated situations, wheat, barley, rye, and different kinds of fruits, are cultivated. Oviedo, Santillana, and St Andero, are the chief towns, besides which, sea-port towns of inferior note are numerous; but the province affords few examples of great commercial activity.

ASYLUM, from the Greek, and signifying a sanctuary, is a place of refuge destined for the protection of criminals, slaves, and debtors. Such sanctuaries have been sanctioned by legislative authority both in ancient and modern times; and to the places usually selected for this purpose, as temples, altars, tombs of distinguished personages, churches, and palaces, a high degree of veneration was attached. The temple, the altar of burnt-offerings, and the six cities of refuge were the chief sanctuaries among the Jews. The famous temple of Diana at Ephesus was a place of refuge for debtors; and the tomb of Theseus afforded a similar sanctuary to slaves. Fugitive slaves, debtors, and criminals of all descriptions, found an asylum in Rome, on a spot chosen by Romulus, between the Capitoline and Palatine mounts. This place of refuge was established and encouraged from political considerations, and for the purpose it is said of adding to the population of the rising city.

Immunities of the same nature were granted to Christian churches in the time of the emperors Honorius and Theodosius, and were afterwards extended to monastic establishments. To a certain extent, and in particular cases, they are preserved in Roman Catholic countries. But in Britain they were entirely abolished at the reformation; and the only sanctuaries protected by law are the verge of the court in England, and the ancient palace of Holyrood-house in Scotland; but the privilege is altogether limited to insolvent persons.

ASYMPTOTE, a geometrical term, applied to a line which continually approaches nearer to another line; but although both lines be indefinitely produced, they never meet. See *Conic Sections*, under Mathematics.

ATALANTIS. See Atlantis.

ATCHIEVEMENT, or Achievement, a term in Heraldry, which denotes the arms of a person or family, along with the external ornaments of the shield, as the helmet, mantle, crest, &c.

ATE, the goddess of discord, according to ancient mythology. The name is derived from the Greek, and signifies *to do hurt*, and she was regarded as the author of all evil. She was the daughter of Jupiter, who was enraged at the dissensions which she excited in heaven, seized her by the hair, and swearing that she should never return, threw her headlong on the earth. This fabulous story teaches that no evil can befal man without the permission of providence, which is supposed to be couched in the representation of Ate being the daughter of Jupiter, and her banishment to the earth as expressive of the awful effects of divine justice among mankind.

ATHAMANTA, Spignel, a genus of plants belonging to the Pentandria class, and to the natural order of umbellated plants.

ATHANASIA, Goldilocks, a genus of plants belonging to the Syngenesia class.

ATHANASIAN CREED, a summary or confession of faith, which was long ascribed to Athanasius, bishop of Alexandria, who flourished in the 4th century. But Dr Waterland supposes, that Hilary, bishop of Arles, is the author of this formulary, which, for more than two centuries, bore the name of an *Exposition of the Creed*, or, simply, the *Catholic Faith*; but as it accorded with the doctrines maintained by Athanasius concerning the Trinity and incarnation, in opposition to the Arians, it received its present appellative designation. See *Critical History of the Athanasian Creed.*

This creed was generally admitted in France about the middle of the 9th century; a hundred years later it was received in Spain and Germany; and satisfactory testimony has been adduced that it was sung alternately in the churches in Britain in the 10th century. About the same time it was adopted in some parts of Italy; but it was not till the early part of the 11th century that it was received at Rome.

ATHANASIUS, St. the zealous defender of the faith against the Arians, was a native of Egypt, and flourished in the 4th century. No record is preserved of his early life, of the progress of his studies, or of the extent of his attainments. But, when he was only a deacon of the church, he accompanied the bishop of Alexandria as his secretary to the council of Nice, which met in 325; and by the force of his arguments, and the power of his eloquence, eminently distinguished himself in the rising controversy with Arius and his followers. In the succeeding year he was nominated to the see of Alexandria, and became the intrepid defender of the catholic doctrine of the Trinity against the Arians; and although he was five times driven into exile, his zeal and ardour in the cause which he had espoused remained unabated. By the intrigues of his adversaries, or the wavering caprices of absolute authority, he was banished by one emperor and restored by another, and oftener than once his abdication and restoration proceeded from the mandate of the same sovereign. During one period of his exile he spent six tedious years in the desert of Thebais. He died in tranquil possession of his see in the year 373. The Historian of the *Decline and Fall of the Roman Empire* thus characterises Athanasius: "Amidst the storms of persecution, he was patient of labour, jealous of fame, and careless of safety; and though his mind was tainted with the contagion of fanaticism, Athanasius displayed a superiority of character and abilities, which would have qualified him much better than the degenerate sons of Constantine for the government of a great empire.——His unpremeditated style, either of speaking or writing, was clear, forcible, and persuasive." The works of Athanasius were printed in 1600 and in 1627; but the most splendid edition was published by Bernard Montfaucon, in three volumes folio.

ATHEISM, from the Greek, and signifying *without God*, is usually defined, the disbelief of a Deity, or of the existence of an intelligent first cause. But the appellation of *atheist* is of more indefinite application. It is not only ascribed to those who are unable to trace the marks of wisdom and design in the universe, which have led all rational inquirers to the acknowledgment of a Supreme Being, but to those who assert that the works of creation afford no such evidence—to those who admit the existence of a creative power, but deny that he is possessed of moral attributes—to those who believe in an evil first principle,—and to those who are attached to pagan idolatry, and to polytheism, or the worship of many gods. It has been doubted whether any man, in the full use of his intellectual powers, ever seriously maintained the disbelief of the existence of a Supreme Being; and where such sentiments have been openly avowed, they have been charged to pride, affectation, or some strange aberration of the mental faculties: "Though a smattering of philosophy," it has been well remarked by Lord Bacon, "may lead a man into atheism, a deep draught will certainly bring him back again to the belief of a God and providence." See Religion. The reader who wishes to be familiar with the arguments which are drawn from the works of nature for the being and attributes of God, may consult with advantage Derham's *Physico-Theology*, Ray's *Wisdom of God*, Paley's *Natural Theology*, and Fenelon's *Demonstration of the Existence of God*, &c.

ATHELING, a Saxon denomination signifying *noble*, was applied by the Anglo-Saxons to the presumptive heir to the crown. This honourable appellation was first conferred by Edward the Confessor on Edgar, to whom he was great uncle, as a mark of distinction, and an expression of his intention that he was destined to succeed him on the throne.

ATHELSTAN, a king of England, of the Saxon race, was the natural son of Edward the elder, and grandson of Alfred, assumed the sovereignty in 925, and reigned 16 years. The liberal and enlightened policy of this prince appears conspicuous in the distinguished privileges assigned to those who were engaged in commercial affairs, and the high consideration in which mercantile intercourse was held. It was formally enacted, that any merchant who had accomplished three voyages on his own account beyond the British channel, should be entitled to the rank and dignity of a thane or gentleman.

ATHENÆA, derived from *Athene*, the Greek name of Minerva, were public festivals celebrated by the ancient Greeks, in honour of that goddess.

ATHENÆA, a genus of plants, belonging to the class Octandria.

ATHENÆUM, a public place of resort, first established at Athens, and dedicated to Minerva. Edifices of this description were constructed in the form of an amphitheatre, and they were frequented by poets and orators, for the purpose of declaiming and reciting their works to the assembled people. A celebrated structure of the same kind was erected by Adrian at Rome; and in modern times a similar denomination is applied to certain literary institutions, where those who are associated for their support are accommodated with newspapers and periodical publications, or have the advantage of books from libraries of a miscellaneous nature, and sometimes of hearing popular lectures on scientific subjects.

ATHENÆUS, a mathematician, who flourished about 200 years before the Christian era, and composed a Treatise on Mechanics, which is yet extant, and forms part of the works of ancient mathematicians, printed at Paris, in folio, in 1693.

ATHENÆUS, a physician who lived about the commencement of the Christian era, and was the founder of the *pneumatic* sect of philosophers. He rejected the prevailing opinion, that fire, air, water, and earth are the true elements of matter, which, he maintained, are derived from heat, cold, moisture, and dryness, their qualities. But to this list he added a fifth element, which he denominated *spirit*, and from this arose the distinctive appellation of the sect. To the agency of this spirit he ascribed the pulsation of the arteries.

ATHENÆUS, a Greek grammarian, was a native of Egypt, flourished in the early part of the third century, and, from some doubtful passages in his writings, it is supposed lived to a great age; but no record of his life is preserved. Numerous works have been ascribed to the labour and industry of Athenæus, among which are specified, "A History of the Kings of Syria," and "An Account of the Illustrious Commanders of Armies;" but the only authentic work which has survived the wrecks of time, and has reached the present day, is a singular production, entitled, "The Deipnosophists," or "Banquet of Philosophers," in which the author has contrived to exhibit a full view of ancient learning and opinions on all subjects. Larensius, a learned Roman citizen, distinguished by his great wealth and excellent taste, is introduced entertaining, at a splendid feast, the celebrated philosophers, professional and literary characters of his time. The various dishes furnish the topics of the miscellaneous conversation, which is conducted in the form of dialogue. Timocrates, one of the guests, makes remarks, and puts numerous questions; and the author himself, who is represented as being present at the entertainment, never fails in his replies to enter into a full discussion of the subject, and in this way displays the wonderful extent of his learning, by descanting on the opinions, the manners, and the domestic arts of the ancients. An edition of this curious work, with a Latin translation, was published in 1597, by the profound critical scholar Casaubon, and as late as 1801 a new edition appeared at Strasburg.

ATHENAGORAS, a Greek philosopher, who flourished about the middle of the 2d century, was greatly distinguished by his learning, and having been converted to Christianity, became a zealous and powerful defender of its doctrines. From Athens, where he had spent the early part of his life, and had acquired considerable reputation for his talents and eloquence, he removed to Alexandria, at that time the most celebrated seminary of learning in the east. At first a keen opponent of the Christian revelation, he carefully examined the arguments and evidence by which it is supported, and being convinced of the truth of its divine origin, openly avowed his belief, and displayed the same ardour and ability in the cause which he had espoused, as in his exertions to resist and subvert the gospel of Christ. The *Remonstrance*, or, as it is sometimes entitled, *Apology*, which he addressed to the Roman emperors, Marcus Aurelius, Antoninus, and Lucius Commodus, against the sufferings and oppressions to which the Christian church was at that time subjected, affords ample testimony of the zeal and erudition which the author employs in its behalf.

ATHENS, the most celebrated city of antiquity, and the capital of Attica, one of the states of Greece, during the long period of its prosperity, shone conspicuous in learning, arts, and political importance, and still exhibits, in its mouldering remains, abundant proofs of its former magnificence.

Like other cities and empires of which no records have existed, or have been preserved, the early history of Athens is involved in obscurity and fable. Ogyges, from whom Attica derived the name of Ogygia, and in whose reign Athens was devoted to Minerva, and was distinguished by her name, was the first king. After a period of several hundred years, Amphictyon held the sovereignty, and instituted the famous assembly of the states of Greece called the *Amphictyonic* Council. The illustrious deeds of Theseus raised him to the first rank of heroes, and the gratitude of his countrymen assigned him a place among the demigods. His immediate successors took an active part in the famous Trojan war; and Codrus, the last king, nobly devoted his life to his country, which, by a decree of the Oracle, could not be delivered from a threatened invasion but by such a sacrifice.

The abolition of royalty, which took place about one thousand years before the Christian era, and had continued for nearly the same period, was succeeded by the institution of archons, a more popular form of government, to whom the direction of the civil and religious affairs of the community was entrusted. The nature, distribution, and extent of the duties of those magistrates, have been detailed under Archon. The election of the archons was at first annual; it was gradually extended to a longer period, and seemed at last destined to become perpetual in the same family. In the struggles for power, on the one hand, and for liberty, on the other, Athens, throughout a long period of her history, was the constant scene of tumult and faction. To repress the prevailing disorders, and to resist the torrent of crimes which threatened to overwhelm the state, the power of framing a code of laws was committed successively to Draco and Solon, names that occupy a prominent place in the records of Greece, famed as they have been, the first for the undue severity, the last for the prudence and wisdom of his enactments. Solon flourished about five hundred years before the Christian era.

When Athens, by the wisdom of her legislators, the patriotism of her citizens, and the bravery and skill of her military commanders, had risen to high political consideration, both at home and abroad, she maintained for many centuries a protracted warfare with the other states of Greece, or with the overwhelming force of the Persians; and, in those repeated contests, the glories of triumph were sometimes exchanged for the ruin and disgrace of defeat. In the rapid strides which were made towards universal dominion by Philip, and his victorious son and successor Alexander, she yielded with the rest of Greece to the sway of the Macedonian monarch. When the Roman power extended to the east, Athens was besieged and taken by Sylla; and under succeeding emperors, as caprice or accident dictated, experienced the liberality and indulgence, or suffered from the oppression and neglect of her foreign rulers. During the reign of Adrian, and some succeeding monarchs, she recovered a large share of her ancient prosperity; her institutions were restored, and some of her splendid edifices were completed or repaired. But the severe destiny which awaited Athens was reserved for the period of Alaric king of the Goths. In the general destruction which marked his progress, the splendour of this renowned city was obscured for ever; her magnificent buildings were converted into a heap of ruins, and for seven centuries the name even was scarcely heard of. Having frequently changed masters, Athens fell at last, in 1455, under the dominion of Mahomet II. The Venetians, in whose hands it had remained for a short time, made two unsuccessful attempts, the first in 1464, and the second in 1684, to recover it from the Turks; but it has since continued in uninterrupted possession of the Ottoman Porte.

In the flourishing periods of its history, Athens acquired unrivalled celebrity for its schools of philosophy, the magnificence of its public buildings, and the progress and perfection to which the fine arts were carried. Even the topographical descriptions of the modern traveller, whose details are confined to fragments and ruins, furnish ample evidence of its ancient splendour.

Athens is divided into an upper and lower city. The upper city, or Acropolis, originally called the *citadel*, included, in early times, the whole population. The situation is elevated, and the sides are precipitous. Thus formed by nature as a place of strength, it has been destined, even down to the present day, to the purposes of a fortress. The entrance to the Acropolis was anciently adorned with the Propylea, a splendid edifice of white marble. The Parthenon, a magnificent temple, dedicated to Minerva, which is esteemed one of the finest specimens of ancient architecture, and is remarkable for simplicity and grandeur of style, has been always regarded as the chief ornament of the Acropolis. Within the same limits is erected the Erectheum, a double temple, with a common portico, dedicated to Neptune and Minerva Polias, a view of which is exhibited on Plate 16. of this work, and the admirers of Grecian art will be gratified in seeing this beautiful example of the Ionic order imitated in the public buildings for the county, now (1816) erecting in the Lawnmarket of Edinburgh, from the elegant designs of Mr Elliot. The Choragic monument of Lysicrates, which stands at the east end of the citadel, is described at page 449, under ARCHITECTURE, and is figured on Plate 17. The same plate presents a view of the Temple of the Winds, a singular structure of the lower city. The examples now alluded to will enable the reader to form some notion of the ancient magnificence of this famous city. The flat country surrounding the Acropolis is also covered with the remains of ancient structures, among which are enumerated the temple of Jupiter Olympius, the temple of Theseus, the Pantheon, the Gymnasium of Ptolemy, &c. The ancient harbours of Athens were, Piræus, distant from the city about four miles, and communicating with it by long walls, part of which is still seen,—Munychia, not far from Piræus—and Phalerum, about the same distance from the city.

Modern Athens lies on the north-east and north of the citadel. The population, composed of Greeks and Turks, is estimated at eleven or twelve thousand. The streets, which do not seem at any period to have been uniform and well arranged, are quite irregular, and the houses, in general, are mean and straggling, while the public buildings present a motely groupe of Turkish mosques and baths, and Greek convents and churches. Athens is situated in N. Lat. 38° 5', and E. Long. 24°.

The splendid collection of Grecian remains made by Lord Elgin, during his residence as British ambassador at Constantinople, and purchased by the nation at the expence of L.30,000 Sterling, and now deposited in the British Museum for public inspection, affords to the artist or admirer of ancient sculpture and architecture every facility of studying and improving his taste on these pure models. For a topographical account of Athens, the reader may consult *Atheniensia*, by Wilkins, 8vo, 1816; Stuart's superb work on its *Ruins*; and for a more general detail of its eventful history, he may be referred to Chandler's *Travels in Greece*, and the *Histories* of Rollin, Mitford, and Gillies.

ATHERINA, a genus of fishes belonging to the order Abdominales. See ICHTHYOLOGY.

ATHERSTONE, or ATHERTONE, a village of Warwickshire, in England, containing about 2600 inhabitants, who are employed in the manufacture of hats, ribbands, and woollen stuffs; and at a fair held in this place, a great deal of cheese is sold.

ATHLETÆ, from a Greek word signifying *combatants*, were persons among the Greeks who were trained to perform in the public games, and, from the nature of the exercises in which they were engaged, were necessarily possessed of great strength and agility. Such were the persons who exhibited their feats in wrestling, boxing, running, &c. at the Olympic, Pythian, and other celebrated games of the ancient Greeks.

To render the Grecian youth hardy and vigorous, and to enable them to bear the fatigues and privations of war, athletic exercises were particular objects of domestic policy. A gymnasium was established in every town, and institutions were appointed at the public expence, for the purpose of exercising young men, and even children, in those games and sports which were thought conducive to a strong and active constitution. The games or exercises common in Greece, were, leaping, wrestling, throwing the dart, the disc or quoit, boxing, and the *pancratium*, or medley of every kind of struggle or active exertion between two combatants.

ATHLONE, a town on the banks of the Shannon, in Ireland, partly in Westmeath and partly in Roscommon counties, and having a commodious communication by a bridge of numerous arches, on which a monument is erected, commemorating the defeat and public execution of some rebellious subjects in the time of Queen Elisabeth. Athlone is 55 miles west from Dublin; and, with a favourable situation, it derives no advantages from trade or manufactures.

ATHOL, the northern district of Perthshire, in Scotland, is a mountainous tract, about 40 miles long;

and 30 broad. Blair-Castle, the residence of the Duke of Athol, and its surrounding gardens and plantations, form a singular contrast with the general aspect of this elevated pastoral region; and the rapid streams of the Tilt, the Gary, and other mountain torrents, afford a striking feature to its picturesque scenery. The pass of Killicrankie, a narrow defile in this district, is noted in history for a battle between the troops of King William and King James, in the end of the 17th century.

ATHOS, a mountain of Macedonia, celebrated in the history and poetry of antiquity, rears its lofty summit far above the elevated promontory on which it reposes, and which projects into the Ægean sea. In the latitude of 40° north, the top of mount Athos is often covered with snow, a certain proof of its great height, which, in the absence of accurate measurement, has been vaguely estimated by some at two miles, or more than 10,000 feet above the level of the sea, and by others has been reduced to little more than 3000 feet.

Mount Athos, now called the *holy mountain*, from numerous bodies of Greek monks, who occupy 24 monasteries erected in different regions, is chiefly to be regarded as a place of religious retirement; and, with the churches and hermitages connected with these institutions, and some fortifications, furnished with cannon and other means of defensive warfare, exhibits to the traveller a striking scene. The monks of Athos were in former times distinguished by their learning, and were once in possession of some curious Greek manuscripts; but they are now more remarkable for poverty than literature, for manual industry in the culture of a rugged soil, than advancement in classical or theological knowledge.

ATLANTIS, or ATLANTICA, a very large island, or rather continent, for it is said to be equal to both Asia and Africa, which is alluded to by Plato in his Timæus, and noticed by other ancient writers, and whose situation is fixed beyond the Pillars of Hercules, the straits of Gades or Gibraltar. The account of such an island is regarded by some as altogether fabulous, while others suppose that the Canary islands, the Azores or Western islands, or even the American continent, is referred to and distinctly indicated in the descriptions of ancient writers; and Rudbeck, a Swedish author, maintains that Sweden and Norway are to be considered the Atlantis of antiquity. Other naturalists hold the opinion, that the Canary Islands and the Azores are merely the remains of the vast continent to which Plato assigned the name of Atlantis; and Mr Whitehurst alleges, that the Atlantis extended from the north of Ireland to the continent of America, and that the Azores islands form the only connecting link which has not been swallowed up by the effects of a convulsion, indications of which are strongly marked at the Giant's Causeway, and the northern coast of Ireland.

ATLAS, a chain of mountains in the north-western regions of Africa, and extending from the shores of the Mediterranean to Lower Susè. To the eastward of Morocco, the elevation is so considerable that they are seen at the distance of 140 miles, and they are covered with perpetual snow. Every variety of climate, from the stern severity of a polar winter to the powerful influence of a summer's sun in tropical regions, prevails in the Atlas mountains; and diversity of elevation exhibits dreary sterility or the rich verdure of luxuriant vegetation. Little is known of the mineral productions of this mountainous range. Granite, and marble of an excellent quality, are spoken of, from which it appears that they are partly at least composed of primitive rocks; and some of the metallic ores have been discovered. That part of the Atlas mountains which lies to the north of Morocco is chiefly inhabited by a robust people called Berebbers, who live in tents, and speak a language peculiar to themselves, and different from the Arabic. The labours of husbandry, and especially the rearing of bees for the honey and wax, are their principal occupations; but that part of the range which stretches southward from Morocco, is occupied by tribes called Shelluhs, engaged in similar pursuits, but different in language, manners, and dress from their northern neighbours, and living in towns and villages.

ATMOSPHERE, from the Greek, and signifying *sphere*, or *circle of vapour*, is the invisible elastic fluid which surrounds the earth, which is necessary for the respiration of animals, the growth of vegetables, and is not less essential to numerous processes of nature and art, which are constantly in a state of activity on the surface of the globe. The constituent parts of the atmosphere, which, by the most accurate experiments, are determined to be 79 of azotic gas, and 21 of oxygen gas;—the aqueous vapour, in an invisible form, which is converted into clouds, or falls in the state of rain, snow, or hail,—its weight or pressure, as it is indicated by the barometer,—its temperature, as it is ascertained by the thermometer,—its height, which is known by optical observations,—and the currents, or winds, to which it is subject, include the chief points of its chemical and natural history. See METEOROLOGY.

ATOM, the minutest particle of matter, beyond which, as the word, derived from the Greek, imports, it is unsusceptible of farther division. The doctrine of atoms, distinguished by the name of *atomical philosophy*, was a favourite subject of speculation with some of the ancient philosophers. First proposed by Moschus, a Phœnician, who lived before the period of the Trojan war, the doctrines of the atomical philosophy were enlarged and extended by Epicurus, and from his name were denominated the *Epicurean philosophy*.

According to the original doctrines on this subject, all the bodies in nature are composed of atoms which are indivisible, impenetrable, and eternal; and the diversity of constitution in natural objects arises from the diversity of arrangement and combination of the same minute particles. But in the Epicurean philosophy the atoms are not only the elements which enter into the composition of all material bodies, but they are endowed with a principle of motion to which are ascribed all the operations of nature; and thus the agency of an intelligent First Cause is excluded from this speculative system.

The atomical theory has been revived of late years by chemical philosophers, in the opinion of some with doubtful advantage, while others maintain that it must prove of the most essential benefit to the science of chemistry. The premature adoption of the doctrine of definite proportions, which was first hinted at by Mr Higgins, and was pursued and extended by Mr Dalton and others, may tend, as it appears to some, to retard rather than to promote accurate investigation, by accomodating the results of analysis to the deductions of theory. But, on the other hand, the establishment of this doctrine fixes chemistry on a sure basis; and it can scarcely be doubted, that a compound exhibiting invariably the same character and properties consists of the same constituent parts, and in the same proportions; but whether even the refined experiments of modern chemistry afford the means of determining with precision those proportions, can perhaps only be known in the future progress of the science.

ATOOI, or Attowa, a large island, belonging to the cluster called Sandwich islands, in the Pacific ocean. See Sandwich Islands.

ATRACTYLIS, Distaff Thistle, a genus of plants belonging to the Syngenesia class.

ATRAGENE, a genus of plants belonging to the class Polyandria.

ATRAPHAXES, a genus of plants belonging to the Hexandria class.

ATREBATES, or Atrebatii, a people of Gaul mentioned by Cæsar as forming part of the Belgic confederacy against him; and from the proportion of troops, stated at 15,000, which they furnished, it would appear that they were distinguished by their power and numbers. When they were forced to submit to the Roman authority, Comius, one of their chief men, ruled over them as the deputy of Cæsar. Arras in Artois, was the seat of the capital of the Atrebates in France.

A people of the same name, supposed to have been a Belgic colony which had settled in Britain before the invasion of Julius Cæsar, occupied part of Berkshire and Oxfordshire in England.

ATREUS, a king of Mycenae in ancient Greece, and the father of Agamemnon and Menelaus, who were very distinguished personages in the history of the Trojan war. Atreus is supposed to have reigned in the 13th century before the Christian era.

ATRIENSES were household servants of the ancient Romans, who are occasionally alluded to by classical writers. They were so denominated from having the superintendance of the *atrium*, or court belonging to the houses of great men, and in particular they were entrusted with the care of the statues and images of the ancestors of their masters, which were arranged round the court, and which, among that people, were objects of great veneration. It was one part of the duty of the Atrienses to carry these images at funeral processions. But it would appear that all domestic concerns came under their charge, and sometimes they were employed as agents or procurators.

ATRIPLEX, Orach, or Sea-Purslane, a genus of plants belonging to the class Polygamia, and of which several species are natives of Britain; one species, *hortensis*, is a common weed in gardens, and some are not unfrequent on sandy shores.

ATROPA, Deadly Nightshade, a genus of plants belonging to the Pentandria class, and of which one species, *Belladonna*, is a native of Britain, but fortunately, as it is a deadly poison, is a rare plant. The berries of a shining black colour, and about the size of a small cherry, are half inclosed within the permanent cup of the flower. The whole plant has a lurid aspect, and, from its general habit, is arranged under the natural order which derives its character from that appearance, and is appropriately called Luridæ.

ATROPHY, derived from the Greek, and signifying *without nourishment*, is a term applied to those diseases in which the body, from deficient nourishment, slowly and gradually wastes away without any violent symptoms. Such is the case in certain diseases of the digestive organs, and particularly in affections of the *mesenteric* glands, in which the progress of the nutriment is retarded or altogether interrupted.

ATROPOS, one of the *Parcæ*, or Fates, according to ancient mythological history, whose office it was to cut the thread of life.

ATTACHMENT, a term in English law, which is applied to a writ or precept issued by order of a court for the apprehension of a man's person, or for the seizure of his goods; and in this, arrest, which extends only to restraint on the person, is different from attachment.

Attachment also signifies a precept of the superior courts for apprehending those who refuse to obey their orders or decrees. See Blackstone's *Commentaries*.

ATTAINDER, a term in law, is the immediate consequence of the sentence of death, which being pronounced, as it is the highest judgment known to the laws of England, the criminal who is the object of it is placed out of the protection of the law, is marked with infamy, and is therefore said to be attainted, that is *stained* or blackened. Attainder only can take place after judgment is pronounced; for even after conviction some plea may be offered in arrest of judgment, by which the effects of attainder are obviated. Attainder becomes effectual by process, by appearance, or by act of parliament; by process, when the criminal escapes and is declared an outlaw; by appearance, in consequence of confession or verdict; and by act of parliament, as in the case of the persons who were guilty of the murder of Charles I. and in others since that period.

Forfeiture of goods and corruption of blood are the consequences of attainder. Blackstone's *Commentaries*.

ATTAINT, is a term in the law of England, and signifies a writ which lies to inquire, whether the verdict pronounced by a jury of twelve men be not false, that the consequent judgment may be reversed. But this mode of proceeding is superseded by a new trial. Blackstone's *Commentaries*.

ATTELABUS, a genus of insects belonging to the order Coleoptera.

ATTENTION is a steady application of the mind to the objects of perception and reflection, for the purpose of obtaining precise information concerning their properties and relations. The word, in its original meaning, signifying *stretching towards*, is strongly and metaphorically expressive of this effort of the mind in contemplating the objects of its consideration. Attention operates in various degrees in different minds and on different occasions. One seems capable of bending his whole mind, for any length of time, to a single object; while another cannot for a moment fix his attention on the same individual objects of perception or thought; and a remarkable occurrence draws forth a strong effort of attention, and makes a deep impression on the mind, but an ordinary incident passes unnoticed, and is soon forgotten.

Various questions have been agitated concerning attention, with regard to its nature and mode of operation; as whether it should be considered as a distinct power of the mind, or merely the exercise or application of its other faculties; and whether the mind, when occupied with the objects of perception or thought, can direct its attention to more than one object at the same instant. Some philosophers who seem not to have fully appreciated the rapid and insensible transitions of the mind in its operations, are disposed to reply to the latter question in the affirmative, and to adopt the opinion that more than one object can be brought under the same mental operation and at the same instant, provided the whole picture of the object be painted on the retina: But it is alleged by others, and with more probability, that attention even to the minutest objects, and to the consideration of their properties and relations, really includes a series of operations which succeed each other with such rapidity that they seem to be only a single instantaneous effort.

ATTENUANTS, or Attenuating Medicines, is a term which is now rather antiquated, and, as the word signifies, is applied to such substances as were supposed to have the effect of diminishing the excessive consistence of the blood and other fluids of the body, which had been produced by disease.

ATTERBURY, Francis, an English divine, who by a rapid career of promotion attained to the see of Rochester, was the son of Dr Lewis Atterbury, rector of Milton in Buckinghamshire. His birth is dated in 1662. At a proper age he became a scholar at Westminster school, was, in 1680, elected a student of Christ's Church college, Oxford, he was admitted, in 1687, to the degree of M. A., and during his residence at college was equally conspicuous for his mental capacity and for his literary acquirements.

The period of his entrance into holy orders has not been recorded; but in 1693 he made an unsuccessful application to be appointed his father's successor; and to spend his days as the rector of his native parish, had hitherto been the ultimate object of his ambition. Disappointed of his object, and disgusted with the dull routine of college duties (which in one of his letters he calls 'the nauseous circle of small affairs,' whence he could derive neither amusement nor instruction,) he resolved to enter on a more active scene of life, and forthwith went to London. He rose rapidly to honour, and to eminence. Chaplain in ordinary to King William and Queen Mary, preacher at Bridewell, lecturer at St Bride's, archdeacon of Totness, doctor of divinity, chaplain in ordinary to Queen Anne, dean of Carlisle, prolocutor of the lower house of Convocation, and dean of Christ's Church, are among the number of the preferments which crowded upon him in rapid succession. And, to crown the whole, on the recommendation of the earl of Oxford, he was, in 1713, advanced to the see of Rochester, and the deanery of Westminster. A man of lofty views, he was not content with the honour, or the influence which this distinguished station conferred, but looked upward with desire to the still higher dignities of the church, and aspired, it is said, to the primateship of all England; and so prudently had he taken his measures, that had a vacancy occurred during the life of the Queen it is probable he would have been archbishop of Canterbury.

But on the accession of George I. to the throne of Great Britain, Atterbury's sun of prosperity began to darken. He had offered the King, on his coronation, the chair of state and royal canopy, perquisites of the deanery of Westminster, which were rejected with evident tokens of dislike to his person. From that time the bishop of Rochester opposed all the measures of the court. He refused to sign the declarations of the bishops against the claims of the house of Stuart; and so strong was the suspicion of his having a share in a plot in favour of the Pretender, that, in 1722, he was apprehended and committed to the tower. In the following year a bill was brought into the House of Commons, which passed into a law, by which he was doomed to perpetual exile. In June 1723 he embarked for France, where, in 1731, he died, as it is supposed of a broken heart, occasioned partly by his degradation and banishment, but chiefly by the death of his daughter. His body was brought to England, and interred in Westminster abbey.

As an author, Atterbury sustained the character of a poet, of a polemic, and of a preacher. His poetical talent was displayed at any early age in a Latin translation of Dryden's Absalom and Ahitophel, in a translation of some of the Odes of Horace, and in an elegant Epigram on the Fan of the Lady whom he afterwards married.

But he soon neglected the muses to court the stern genius of controversy. His first essay, in this department, was in defence of the Reformation, and in vindication of the character of Luther, its illustrious champion. The severest contest which he sustained was with Dr Wake, respecting the rights, powers, and privileges of the clergy. Dr Wake, who was afterwards archbishop of Canterbury, had endeavoured to prove, that the right of convening the clergy was vested in the prince;—that they can discuss nothing without his permission;—that his power over their constitution and decrees was supreme;—and that he alone can dissolve their synods. In opposition to these positions, Atterbury maintained, that the clergy have a right to meet and deliberate independently of any superior power; and treats his antagonist's book 'as a shallow empty performance, written without any knowledge of our constitution, or skill in the particular subject of debate.' In consequence of the zeal which he displayed in this curious controversy, he was viewed by the one party as a man of a hot and acrimonious mind, and treated with a large portion of abuse; while, by the other side, he was regarded as an able advocate of high church principles, and received the thanks of the lower house of Convocation, and the degree of doctor in divinity from the university of Oxford. Besides these disputes, some of the doctrines which he had taught in his sermons, particularly that of passive obedience, were called in question by Mr Hoadly, which engaged him in a controversy with that divine. A view of these disputes, with copious extracts, will be found in the Biographia Britannica.

As his eloquent sermons, and impressive manner of preaching, first brought the bishop of Rochester into notice, so his character as an author must be estimated from his compositions of this description, which have been long before the public, and which are still read as specimens of genuine pulpit eloquence. His sermons, contained in four octavo volumes, embrace a variety of topics, which are treated with great clearness, simplicity, and warmth of expression. He speaks both to the understanding and the heart of his hearers; and as he possessed a keen and ardent mind, and an animated countenance, he must have been heard with attention. Let the violence of this great man's temper, which the heat of controversy provoked; let the party zeal which he displayed, and which some think is rendered excuseable by the turbulence of the times, be buried in oblivion, and let us learn diligence from his example, and piety and virtue from his works.

ATTICA, a peninsular region of ancient Greece, having Peloponnesus for its boundary on the west, the Ægean sea and the Saronic gulf for its limits on other two sides, and united by land with Bœotia; derived more of its celebrity from Athens, the capital, than from the whole state; and, indeed, the ancient splendour of the latter seems to have sunk the former into comparative obscurity. Eleusis, Sunium, and Marathon are its other chief towns, some of which are connected with the most celebrated exploits recorded in Grecian history. Attica is described as a barren district. Among its vegetable productions the olive has been famous from the earliest times to the present day; and the abundance and excellence of the honey of Mount Hymettus have been well known in all ages. See GREECE.

ATTILA, the celebrated king of the Huns, who assumed the reigns of government in 433, was remarkable for the deformity and strength of his body, and the boldness and fierceness of his look, for his military prowess, and the immense armies, amounting to 500,000, or, according to some accounts, to 700,000 barbarians, which obeyed his command, and the vast extent of empire, stretching from the borders of China to the banks of the Danube, over which he swayed the sceptre of uncontrouled authority. The cruelty and barbarity which accompanied his numerous and extensive conquests, imposed upon him the reproachful designation of the *Scourge of God*. From a peculiar habit which he had acquired of fiercely rolling his eyes, it is supposed that he wished to inspire terror in those who were near his person. 'The crowd of the vulgar kings, (says Gibbon,) the leaders of so many martial tribes, who served under the standard of Attila, were ranged in the submissive order of guards and domestics around him. They watched his nod, trembled at his frown, and at the first signal of his will executed, without murmur or hesitation, his stern and absolute commands."

His death, which happened about the year 453, was attended with singular circumstances. He had married a new wife, a beautiful virgin; the nuptials were celebrated with great pomp and festivity, at his palace beyond the Danube, and he retired late to bed oppressed with wine. A blood-vessel in the lungs burst in the night, and produced suffocation. In the morning the bride was found sitting by the bed-side, overwhelmed with tears and lamentations at the sudden event, and the danger which probably awaited her. "The body of Attila was exposed in the plain, while the Huns, singing funeral songs to his praise, marched round it in martial order. Enclosed in three coffins of gold, silver, and iron, it was privately interred during the night; and to prevent the violation of his remains by the discovery of the place where he was buried, all the captive slaves who were employed in the solemnity were barbarously massacred." Gibbon's *Roman History*.

ATTORNEY, a person who transacts any business in place of another, either in a public or private capacity. In the latter case he is appointed by *letter of attorney*, and in the former he manages the law proceedings of his client by warrant or authority from him; and in this character he is denominated *Attorney-at-Law*.

Attornies-at-law must be formally admitted and sworn into the particular courts in which they practise. A practitioner in the court of King's Bench cannot appear in the court of Common Pleas; an attorney in the latter cannot act in the former; and to practise in the court of Chancery he must be regularly admitted a solicitor in that court. Attornies are regarded as members of their own courts, are subject to the regulation and animadversion of the judges, and, at the same time, enjoy many valuable privileges. Without being admitted in a superior court of record, no person can act as an attorney at the court of Quarter-Sessions. Blackstone's *Commentaries*.

ATTORNEY-GENERAL is the great law-officer of the crown in England, and is appointed to his office by the king's letters patent. It is the duty of the attorney-general to exhibit informations, and to prosecute for the crown in criminal matters, and to file bills in the Exchequer for any thing concerning the king in inheritance or profits.

ATTRACTION, is a general term in natural philosophy to denote that power by which all bodies tend to each other. This power or property pervades all nature. It operates on the minutest particles, as well as on the largest masses of matter, and under various modifications has received different names. When it acts at sensible distances, as when the planets of the solar system are drawn towards the sun, or when a stone unsupported falls to the ground, it is distinguished by the general name of the *attraction of gravitation*. When two polished surfaces of glass, marble, or metal, are brought into close contact by the exclusion of the air, they are strongly drawn towards each other, and this modification of attraction is called *adhesion*. When particles of matter of the same kind are united, the power which operates is denominated the *attraction of aggregation*, or *cohesion*. But when the minute particles of matter of different kinds enter into combination, as oil of vitriol, or sulphuric acid and soda, a new compound, totally different in its character from its constituent elements, or the familiar substance, Glauber's salt, is obtained; and this constitutes the true character of chemical attraction or affinity, where the particles of matter act on each other at insensible distances. See *Affinity*, under CHEMISTRY, and *Universal Gravitation*, under ASTRONOMY.

ATTRIBUTE, in its general meaning, is a quality or property essential to the nature of a person or thing. Understanding is said to be an attribute of mind, and extension is an attribute of matter.

ATTRIBUTES of God, are those perfections which belong to the character of the Supreme Being, as his infinite power, wisdom, justice, and goodness.

ATWOOD, GEORGE, an English mathematician and natural philosopher of considerable eminence, was born about the year 1745, was educated at Westminster school, and prosecuted his studies at Cambridge with so much success that he became a fellow of Trinity college, and afterwards one of the tutors. He delivered lectures on experimental philosophy at Cambridge for several years, which were numerously attended and greatly admired; and having given up his residence at the university, he was much employed in financial calculations by the late Mr Pitt, who appointed him to a sinecure office for the purpose of retaining his services in that department of his political arrangements. Mr Atwood died in London in 1807, when he had reached the 62d year of his age.

The scientific labours of Mr Atwood were chiefly employed on physical subjects; and his investigations on *Rectilinear Motion and Rotation of Bodies*, on *the Stability of Ships and Floating Bodies*, on *the Construction of Arches*, &c. with an *Analysis of a Course of Lectures*, and a Description of Experiments for their illustration, and a Review of the Regulations for the *Assize of Bread*, were published in detached treatises, or in memoirs in the Philosophical Transactions. He was also the inventor of an ingenious apparatus for illustrating experimentally the doctrine of accelerated and retarded motion, or determining the quantity of matter, the moving force, the space described, the time of description, and the velocity acquired by a falling body.

AVA, an extensive kingdom of Asia, in the peninsula beyond the Ganges, having Tonquin and Cochin-China on the east, and China and Thibet on the north, is well watered by numerous streams, and abounds in vegetable productions. The territory of Ava is now included in the Birman empire. See BIRMAH.

AVA, the capital of the kingdom of Ava, was formerly a flourishing city, but is now falling to decay since the seat of government has been removed to Ummerapoora, which is the present capital of the Birman empire. Ava, which stands on the banks of the river Irrawaddy, was once four miles in circumference, and was defended by a wall and ditch; but its roofless houses, ruined temples, and deserted streets, present a melancholy contrast with its former prosperity.

AVALANCHES are huge masses of snow, which are detached from the base on which they rest in Alpine regions, and chiefly in the Alps of Switzerland, partly by the melting of the snow, and the water thus generated being conveyed through fissures, producing a separation between the side of the mountain and the inferior stratum of snow, and partly, it seems probable, by the heat of the earth dissolving the lower stratum, and are precipitated, by their incumbent weight, into the vallies below, overwhelming forests, fields, and villages. Some of these masses of frozen snow, 200 feet in diameter, have been observed.

AUBAINE, or *droit d'Aubaine*, was a right claimed by the kings of France to the inheritance of foreigners who died within their territory. The Swiss, Savoyards, Portuguese, and Scots, who were considered natives of France, and ambassadors from foreign states, were exempted.

AUBE, a department of France, which is thus denominated from a river of the same name by which it is traversed, is bounded on the north by the department of the Marne, and on the west by that of the Seine and Marne; part is covered with forests, part of it is abundantly fertile in grain and fruits, and part is remarkable for its sterility. The population exceeds 240,000, and Troyes is the capital.

AUBLETIA, a genus of plants which belongs to the Polyandria class, and derives its name from M. Aublet, a learned French naturalist, who is the author of an elaborate work on the plants of Guiana.

AUCH, the capital of the department of Gers in France, and formerly the chief town of Gascony, stands on a declivity near the river Gers, is about 400 miles south-west from Paris, and contains nearly 8000 inhabitants. The streets are narrow, but clean and well paved, and some of the modern buildings are not without elegance. The archbishop's palace is a princely structure; and the cathedral, which is remarkable for the rich profusion of its internal decorations, is described as one of the most magnificent edifices in France.

AUCKLAND, or BISHOPS AUCKLAND, a borough town of the county of Durham in England, derives its first name from the forest of oaks formerly in its vicinity, and the additional appellation from the palace, which is the residence of the bishops of Durham; stands on an elevated spot near the confluence of the Wear and Wandless, and contains nearly 2000 inhabitants, part of whom is employed in manufactures, especially in the printing of calico and other cotton stuffs.

AUDE, a department of France, having the Pyrenees on the south, and the sea on the east, and traversed by a river of the same name, has a tolerably fertile soil, and some extensive forests, is famous for its honey, contains a population exceeding 226,000, and Carcassone is the capital.

AUDRAN, CLAUDE, a French engraver, who was born at Paris in 1592, and having attained the venerable age of 85, died at Lyons in 1677, was less distinguished as an artist than as being the first of a long race of the same name in the same profession, and as being the father of three sons, some of whom rose to great eminence. The brother, or, according to some accounts, the cousin of Claude Audran, was also a respectable engraver; and his prints of the *Annunciation* from Hannibal Carracci, and the *Assumption* from Domenichino, are still regarded as excellent productions.

AUDRAN, Gerard, the third son of Claude Audran, was born at Lyons in 1640, and died at Paris in 1703. He was by far the most celebrated artist of this remarkable family, and executed some highly prized engravings from pictures by the first masters. But the powers of his art shine conspicuous in the *Battles of Alexander*, which are universally admired as wonderful productions of the graver, and in which it has been strongly expressed, that he surpassed even the expectations of the painter himself. The prints alluded to are *the passage of the Granicus; the battle of Arbela;* and *Porus brought to Alexander, after his defeat*,—all of large size, from pictures by Le Brun: To this series were added two others, from pictures by the same artist; namely, *Alexander entering the tent of Darius*, which was engraved by Gerard Edelink, and *the triumphal entry of Alexander into Babylon*, executed by Audran. It may be worth while that the admirer of these splendid engravings should recollect that the impressions in highest estimation are marked with the name of Goyton the printer.

AVEBURY, or Abury, a village of Wiltshire in England, is about nineteen miles north from Stonehenge, and is famous for its druidical temple, the scanty remains of which still exhibit a singular monument of British antiquity. Surrounded by a ditch and rampart, this sacred structure was composed of several concentric circles, with a central obelisk, and two avenues, one of which led to the south-east and the other to the west; the whole consisting of single stones placed perpendicularly in the ground, and rising from ten to nineteen feet above the surface. The avenues, formed of 200 upright stones were a mile long; and the structure, when entire is supposed to have been composed of not fewer than 650 stones. See Britton's *Beauties of Wiltshire*, Vol. III.

AVEIRO, or New Braganza, a sea-port town in the province of Beira in Portugal, stands in a flat marshy country, and contains nearly 5000 inhabitants. The river Vouga traverses the town, but the shallowness of the water admits only vessels of small size. The trade is inconsiderable, but the fishery, which supplies the province with sardinhos, is a copious source of employment and profit to a large portion of the population, and the manufacture of salt in the vicinity is extensive.

AVELLINO, a town of Naples, is situated on the declivity of a hill, and contains about 9000 inhabitants, who are chiefly employed in the manufacture of woollen cloth, wooden chairs, maccaroni, and pastes of different kinds, the latter of which are in great esteem throughout the surrounding country. The soil of the district, which is chiefly of a volcanic nature, is unfavourable to the production of corn; but fruits are abundant, and the cultivation of the Spanish filbert is so successfully conducted, that the amount of produce, in a good season, exceeds 11,000l. Sterling. The trees are planted in regular rows, and are carefully trained and dressed.

AVENA, Oats, a genus of plants belonging to the class Triandria, and including the cultivated oat with its numerous varieties, the wild oat, and some other species, which are natives of Britain.

AVENCHE, an ancient town in the canton of Berne in Switzerland, stands at the southern extremity of the lake Morat, and is now chiefly remarkable for the splendid remains of its former magnificence, which are scattered in great profusion within a circuit of five miles; among which are enumerated fragments of an amphitheatre, the floor of a bath, executed in mosaic work, and adorned with human figures, cornices of white marble sculptured with urns, griffins, and sea-horses, and a stupendous column of white marble, sixty feet in height, all which afford certain evidence of this place having been a favourite residence of the ancient Romans. Coxe's *Travels in Switzerland*.

AVENZOAR, an Arabian physician, and one of the earliest writers on medicine, flourished about the end of the 11th century, was born in Spain, and belonged to a family, in which the profession seemed to be hereditary. He lived, it is said, to the great age of 135; and the splendour of his talents and acquirements, or the extravagance of fulsome adulation, called forth from his cotemporary, and supposed pupil, Averroes, the lofty titles of "*Admirable, glorious, the treasure of all knowledge, and the most supreme in physic.*"

AVERNUS, a famous lake, not far distant from Puzzuoli in Campania in Italy, the exhalations of which were supposed to have been of so pestilential a nature that no animal could approach it with safety; and even birds flying across its surface were suffocated by its vapours and dropped down dead. The more accurate observations of modern naturalists have completely subverted the erroneous information concerning this lake and others to which similar effects were ascribed, and which were drawn from the groundless details of mythology, or the fancied descriptions of poetry. Lake Avernus in Italy was supposed to be bottomless, two miles long, and about a mile broad. The depth is ascertained to be less than 200 feet; and it presents a fine expanse of limpid water abounding with fish. A gloomy cave on its banks is described by Virgil as the residence of the Cumean Sybil.

AVERROES, an Arabian philosopher, was born about the beginning of the 12th century at Cordova, in Spain, then the capital of the Moorish territory in that country, was educated in the university of Morocco, and became so eminent in mathematics, law, medicine, and divinity, that he was regarded as one of the first philosophers of the age. He was particularly celebrated by his elaborate annotations on the works of Aristotle, and was long known in the schools by the distinctive appellation of the Commentator; and was not less notorious for his indiscriminate rejection of every religious creed, Jewish, Christian, and Mahometan.

AVEYRON, a department of France, watered by a river of the same name, has the department of Tarn on the south, and that of Cantal on the north. The surface and soil are more suited for pasture, and the rearing of numerous herds of cattle, than for the culture of grain. Hemp is extensively cultivated, and the vine grows luxuriantly. Coal, alum, and the ores of iron, lead, and copper, are enumerated among the mineral productions. The population exceeds 326,000, and Rhodes is the capital.

AUGITE, a crystallized mineral, belonging to the siliceous genus, and a native of basaltic rocks. See MINERALOGY.

AUGSBURG, the *Augusta Vindelicorum* of the Romans, a city in Swabia in Germany, stands in a fertile and beautiful plain near the confluence of the rivers Lech and Werlach, and is 300 miles west from Vienna, and 40 miles north-west from Munich. The trade of this city was in former times most prosperous, and some of its merchants were the wealthiest citizens in the empire; but it has now greatly declined. The population is estimated at more than 30,000, who are occupied in various kinds of manufactures, as those of cotton stuffs, leather, paper, dyeing, bleaching, gold and silver lace, clocks and watches, and toys. Literary labour, once respectable in Augsburg, is now confined to the production of religious tracts for children and the common people, picture books of a similar description, and cheap maps. Two-thirds of the inhabitants are Roman catholics, and the rest are Protestants; and it is only since the commencement of the present century that Jews were permitted to reside within its walls.

The streets are regular and spacious; the houses are constructed partly of wood and partly of freestone; and some of the churches, and other public buildings, can boast of great elegance, and a profusion of rich ornaments. The town-house is a magnificent edifice, adorned with a splendid marble portico, and numerous brazen figures of animals richly gilt; and the public fountains are equally ornamental and beneficial to the city. The fountain of Augustus is a fanciful structure, composed of figures of brass in the form of men, women, children, dolphins, and sphinxes, and from the centre rises a pedestal surmounted by a statue of Augustus of the size of life. Augustus Cæsar is regarded as the founder of the city, and from him it derives its name. An aqueduct conveys the waters of the Lech to the city for the supply of the fountains, and for communicating motion to the machinery of various manufactories.

Augsburg suffered greatly during the French revolutionary war, from the various fortunes of the contending powers, and was at last attached to the kingdom of Bavaria.

Augsburg Confession.—But this city holds a most conspicuous place in history, in consequence of the famous diet which met in it, and at which the Lutheran confession of faith, hence called the Augsburg *Confession*, was presented to the emperor Charles V. This diet assembled in 1530; and the confederate princes who espoused the cause of reformation, and had protested against the decree of the imperial diet of Spires, passed a few months before, first assumed the distinctive appellation of *Protestants*. This celebrated confession, which was drawn up by Melancthon, the coadjutor of Luther, consists of 20 chapters, containing a detailed view of the religious creed of the reformers, and the reasons of their separation

from the church of Rome. It was read in the public hall, in presence of the Catholic and Protestant divines; and although some modifications were made on objectionable clauses, and the influence of the emperor was interposed, yet the conference produced no reconciliation. Some of the Protestants themselves disapproved of parts of the confession, separated from the Lutherans, and assumed the name of *Evangelical Reformed*, by which denomination a large proportion of the German Protestants is at this day distinguished. See Robertson's *History of Charles V.*

AUGURY, a kind of divination, or mode of fortelling the nature of future events, by observing the manner of feeding, the flight, and the chattering or singing of birds. It was practised by the ancients, and especially by the Romans, who rarely undertook any important affairs without previously consulting those who studied and superintended the system of augury, which ignorance and superstition had established among that people.

Augury was practised among the Romans in the earliest period of the state. Romulus appointed three augurs of patrician or noble rank. When the influence of the people had increased in the commonwealth, the college of augurs was enlarged to nine, four of whom were chosen from the Patricians, and five from the Plebeians. Six were afterwards added to the number; and the institution, now composed of fifteen members, continued to be held in high respect and dignity during the prosperous periods of Rome. The augurs were next in dignity to the order of priests; they were clothed in splendid robes of purple and scarlet; they wore a cap of a conical form; and while they exercised their mysterious functions they held the *lituus*, or divining rod, which was a crooked staff, in their hand.

The Roman augurs, aware of the imperfection of their system of divination when they trusted for the exercise of their art to the casual and uncertain motions of wild birds, not always within their observation, improved and refined upon it by keeping a number of chickens, to which the epithet of *sacred* was added, and from their motions and manner of feeding they could at all times predict the good or bad fortune of those who consulted them on future events.

Augury, although not formally practised in the present day, is not yet entirely eradicated from the human mind. The lights of science and religion, and the general diffusion of knowledge, have not been able to dispel the gloomy forebodings which are excited by the actions of some of the feathered tribes. The crowing of a cock at an unusual hour, is regarded by many as an ominous presage; and to the weak and superstitious, the croaking of the raven, in certain circumstances, and the screaming of the night-owl, are the awful harbingers of misfortune.

AUGUST, the eighth month of the year, according to the modern kalendar, was the *sextilis*, or sixth month of the Romans, reckoning from March, the commencement of their year, but was changed to his own name by Augustus Cæsar, because that month had been peculiarly favourable to his fortunes.

AUGUSTA, a town of Sicily, which stands on a peninsular spot on the eastern coast, and not far distant from the ruins of ancient Megara, was almost entirely destroyed in 1673 by an earthquake, has been since rebuilt with low houses, to obviate, in some degree, the dangers of similar accidents; contains about 15,000 inhabitants, and in former times served as a depot for the ships belonging to the knights of Malta to be supplied with stores and provisions.

AUGUSTINE, St. a learned bishop of the early Christian church, was a native of a small town in the interior of Numidia in Africa, and was born in the year 354, made rapid progress in his studies, and, while yet a youth, opened a school of grammar and rhetoric in his native place, and acquired great reputation by his public lectures on the same subject, which he delivered at Carthage, Rome, and Milan. Some doubts which he had entertained concerning the doctrines of Christianity were removed by hearing the eloquent sermons of St Ambrose, bishop of Milan, and from him he received baptism. Returning to Africa, and being ordained a presbyter, by Valerius, bishop of Hippo, he was afterwards associated with him in his episcopal functions. But before this period he and some friends had devoted themselves to retirement, fasting, and meditation, and having all things in common, subjected themselves to all the austerities and privations of the monastic life. St Augustine died in 430. His early life exhibited a scene of dissipation and licentiousness; but his maturer age was exemplary for virtuous conduct and the zealous discharge of all the duties of a Christian instructor. His works have been printed in ten volumes.

The ascetic life of St Augustine is the origin of the various orders of monastic institutions which have assumed his name. Soon after their regular establishment in the 13th century, the religious order of Augustine, or Austin friars, was introduced into England, and at the time of their suppression, in the 16th century, 32 establishments of the kind existed.

AUGUSTUS, the appellation conferred by the senate on Cæsar Octavianus, the first Roman emperor. The obscure name of *Octavianus* was derived from a family of no rank. "The illustrious name of Cæsar," Mr Gibbon observes, "he had assumed as the adopted son of the dictator; but he had too much good sense to hope to be confounded, or to wish to be compared with that extraordinary man. It was proposed in the senate to dignify their minister with a new appellation; and, after a very serious discussion, that of Augustus was chosen among several others, as being the most expressive of the character of peace and sanctity which he uniformly affected. *Augustus* was therefore a personal, *Cæsar* a family distinction." The first was the sacred title reserved for the monarch, the second was usually communicated to his relations, and, from the reign of Adrian, was appropriated to the second person in the state, who was regarded as the presumptive heir of the empire.

AVICENNA, pompously styled the prince of Arabian philosophers and physicians, flourished in the end of the 10th and beginning of the 11th century, in his earliest years had made great proficiency in grammar and the knowledge of the koran, and, as his intellectual powers were matured, became no less distinguished in mathematics and other branches of learning which were then the objects of pursuit and study. Like the philosophers of the age, Avicenna lived a wandering and unsettled life; now basking in the sunshine of prosperity at the courts of princes, now a houseless fugitive, exposed to all the rigours of adversity; now immersed in licentious pleasures, and now devoted to profound study. He died in the year 1036. The works of Avicenna on mathematics, metaphysics, morals, theology, natural history, and other subjects, are extremely voluminous; but the laborious undertaking of an Encyclopædia, or general view of human knowledge, which he dignified with the quaint and expressive title of the *Utility of Utilities*, and which, it is said, was projected in his 21st year, and soon executed in 20 volumes, is of itself a gigantic performance, and affords sufficient evidence of a vigorous mind and indefatigable industry. While scholastic philosophy and divinity were held in repute, the works of Avicenna were much read and greatly admired.

AVICENNIA, or Eastern Anacardium, a genus of plants belonging to the Didynamia class.

AVIGNON, the capital of the department of Vaucluse in France, stands on the eastern bank of the Rhone, is surrounded by battlements which include a circuit of three miles, and contains about 30,000 inhabitants. The streets have no claim to regularity or beauty; but the public edifices in their decaying grandeur still display striking marks of their former magnificence. Some of the churches are adorned with monuments which, in elegance of design and perfection of execution, have been rarely surpassed, and with paintings which have been always ranked among the finest productions of the pencil. The defaced tomb of Laura, the celebrated object of Petrarch's hopeless passion, and of her husband, in the church of the Cordeliers, is still visited by the curious stranger; and in a valley five miles from the city is the fountain of Vaucluse, of poetical celebrity, the retirement which Petrarch often sought to indulge his grief and misplaced affection. The pointed extremity of a projecting rock near the fountain, is surmounted by the remains of an ancient tower, which is still denominated the *castle of Petrarch*.

Avignon is conspicuous in history, as the residence of the papal see for a period of 70 years, from the time that Clement V. transferred it from Rome in 1309; and when the head of the Catholic church restored his court to the Vatican, a rival pope held a divided sovereignty in Avignon, till Martin V. succeeded in the year 1418, when it was erected into an archbishopric, and continued to be part of the ecclesiastical territory till the late revolution in France, when it was attached to the new republic.

AVILA, a city of Old Castile in Spain, stands in a spacious plain, surrounded with mountains, and covered with orchards and vineyards, is walled and fortified, contains about 2000 houses, many of which are well built, an university, numerous religious houses, and a magnificent cathedral; and some of the inhabitants are occupied in the cloth manufacture.

AUK, the name of a bird belonging to the order Anseres. See *Alca*, under Ornithology.

AUKLAND BISHOPS. See Auckland.

AULUS GELLIUS, a learned Roman, who flourished in the time of Adrian and the Antonines. He was a native of Rome, and as was the custom of the period in which he lived, he resided some time in Athens, for the purpose of prosecuting his studies at that celebrated school of philosophy. Having visited some of the other Grecian states, he returned to his native city, and rose to eminence in the profession of the law.

The *Noctes Atticae*, "Athenian Nights," the only production of Gellius known at the present day, was begun while he resided at Athens, and is a curious literary miscellany, containing various biographical, historical, and critical observations on ancient authors and passages of their works, and exhibiting an instructive picture of the manners, customs, and opinions of antiquity. Various editions of this work have appeared, but the English reader has an opportunity of perusing it, and appreciating its merits, in a translation by Mr Beloe, published in 1795.

AVOCADO PEAR, the trivial name of the *Laurus persica*, a rich fruit of the West Indies, which, from its nutritious qualities, and resemblance to marrow, has been called *vegetable marrow*.

AURANCHES, or AVRANCHES, an ancient town of lower Normandy, now the department of the Channel, in France, contains about 5000 inhabitants, and is chiefly remarkable for the extensive ruins of the castle, and the lofty station of the cathedral, part of which occupies the extreme verge of an overhanging precipice. The stone on which Henry II. of England knelt when he received absolution from the Pope's nuncio for the murder of Thomas a Becket, in 1172, is said to be still preserved at the cathedral, and is pointed out to strangers as a curious relic.

AURANTIUM, the specific name of the orange tree in the Linnæan classification of plants.

AURELIA, the name by which insects are distinguished in one of the stages of their transformation by older naturalists, and analogous to the more modern appellation *Chrysalis*. See ENTOMOLOGY.

AURELIAN, or AURELIANUS LUCIUS DOMITIUS, one of the most powerful and celebrated of the Roman emperors, rose from the humble station of the son of a peasant in Pannonia, and from the rank of a common soldier, in which capacity he entered the army, to the exalted dignity of head of the empire, not less by his personal courage than by his military skill and prudent conduct. Having passed through the various subordinate ranks, he obtained the chief command of the army under Claudian, and acquired such reputation and influence that, on the death of that emperor, the irresistible voice of the soldiers, who shared his glory and his conquests, nominated him his successor, and in the year 270 placed him on the throne. Every territory, even the most distant which the Roman power had reached, was a witness of his triumphs. In his rapid and unexampled progress, the Persians and Egyptians, the Goths and the Vandals, were discomfited; and Spain, Gaul, and Britain, yielded to the force of his arms. But his power was not raised on a solid foundation. The discontents and murmurs of the higher orders of the people, excited by his marked partiality to the Plebeian rank, which he could not conceal, broke out into open and dangerous insurrection, in the suppression of which he displayed the cruelty and barbarity which, it is said, were natural to his disposition. In the commencement of the year 275, while he conducted a powerful army against Persia, one of his secretaries, who dreaded the punishment of extortion, had the address to persuade the chief officers that they were all involved in a general proscription. Watching the first favourable opportunity, they attacked him on the march from Byzantium, and he fell covered with wounds. The fraud was discovered when too late; but the traitor was exposed to the fury of wild beasts, and the funeral obsequies of the emperor were celebrated with great pomp and magnificence. Gibbon's *Roman History*.

AURENG-ZEBE, the great Mogul, one of the most successful conquerors and celebrated sovereigns of the empire of Hindostan, was the third son of Shaw Jehan, whom he succeeded on the throne, and was born in 1618. Actuated by strong ambition, Aureng-zebe was one of those who

—— wade through slaughter to a throne.

Under the humble garb of a religious recluse, he acquired a high character for sanctity among his countrymen, while he was concerting measures for securing to himself the sovereignty. But before he reached the summit of his boundless wishes, three of his brothers were doomed to be the victims of barbarous assassination. He was proclaimed emperor in 1659, during his father's lifetime; and when he had obtained the undivided possession of the throne of Delhi, no rival appeared to disturb the profound tranquillity which reigned throughout the empire for the long period of twenty years. But his exertions to convert his Hindoo subjects to the Mahometan faith excited tumults and insurrections in various parts of his dominions, and kept him, during the latter years of his life, in constant disquiet and alarm. He had succeeded in the reduction of some of the insurgent states; but while he had retired to winter quarters at Ahmednagur, he was seized with an illness which proved fatal in 1707, and when he had reached the 90th year of his age. By his own directions, his body was deposited in the tomb of a holy dervise, without pomp or ornament. His memory is held in great veneration by the Mahometans; and his tomb is the frequent resort of pilgrims, for the purpose of performing their devotions. Dow's *History of Hindostan*.

AURIPIGMENTUM, signifying *pigment*, or *paint of gold*, or orpiment, is an old name for sulphuret of arsenic, a common ore of that metal. See MINERALOGY.

AURORA, the morning twilight, or the faint light which precedes sun-rising; and, in ancient mythology, the goddess of the morning, who is represented by the poets in a chariot rising from the ocean, with rosy fingers dropping dew. In Virgil's description of the goddess of the morning, she is drawn by four horses in a flame-coloured chariot.

AURORA BOREALIS, NORTHERN LIGHTS, or, according to the vulgar appellation, *Streamers*, or *Merry Dancers*, a luminous meteoric appearance, which is observed most frequently in frosty weather in northern regions of the atmosphere, and hence the origin of its first name, which is become less appropriate since the discovery and description of a similar appearance in high southern latitudes by Mr Forster, the naturalist who accompanied Captain Cook in his second voyage round the world. It is a curious fact in the history of this meteor, that, with the exception of some doubtful descriptions by Aristotle and Pliny which seem to refer to it, observations on the *aurora borealis* are limited comparatively to modern times. The first on record was observed in January 1560, and is mentioned under the descriptive appellation of burning spears. It was again seen in 1564 and 1574 in England, in 1575 in Brabant, and in 1580 and 1581 in some parts of Germany; in 1621 it was observed all over France; and in 1623 it was seen throughout the greater part of Germany; but from that time, during a period of eighty years, no record exists of any such appearance. It reappeared for a short time in Ireland in 1707, and was seen in the same and the succeeding year in Denmark. But the *aurora* which was observed in 1716, and is minutely described by Dr Halley, was remarkable for its brilliancy and extent. It was visible from the west of Ireland to the east of Poland, and from the 50th degree of north latitude throughout all the northern regions of Europe.

The *aurora borealis* has been variously ascribed to electricity, to magnetism, to a phosphorescent light, to the light of the sun repeatedly reflected from different regions of the clouds, to the zodiacal light, and to the inflammation of hydrogen gas, which, as Mr Kirwan, who proposes the theory, thinks, is generated in great abundance in various natural processes in the equatorial parts of the globe, and by its low specific gravity ascends rapidly into the atmosphere, and is kindled by electricity. But the true explanation of this meteor is still involved in obscurity. See METEOROLOGY.

AURUM, Gold, one of the precious metals; for the natural and chemical history of which, see CHEMISTRY and MINERALOGY.

AUSONIA, the ancient name of Italy, which is sometimes employed by the poets, and is derived from the early inhabitants, who were called Ausones.

AUSONIUS DECIMUS, or DECIUS MAGNUS, a Latin poet of the fourth century, was born at Bourdeaux in France, was educated under the care of a relation, professor of rhetoric at Thoulouse; and having made unusual progress in his studies, he returned to his native place, where he successfully taught grammar and rhetoric. The fame of his lectures reached the imperial court, and secured to him the good fortune of being appointed by Valentinian to superintend the instruction of his son Gratian; and as a requital for his services, he was raised to the chief offices of the state, first to that of quæstor, and afterwards to the distinguished station of consul. He stood high in favour with the emperor Theodosius, who promoted him to the patrician dignity, and urged him to publish his poetical works. He died near the end of the fourth century. The genius and poetry of Ausonius are allowed to be of a superior character to his cotemporaries. The edition of his works, with a French translation, published at Paris in 1769, in four small volumes, is reckoned one of the best.

AUSPEX, an appellation originally applied to the Roman augurs, or those who predicted future events from observing the flight of birds; but according to some, it was less limited in its application, and denoted generally any person who interpreted omens.

Auspices were consulted on all matters of importance by the ancient Romans; and it seems probable, that the system became a political engine which generals and statesmen employed for the purpose of facilitating or retarding those enterprises in which they were engaged, as best suited their views. Assemblies of the people were not legally constituted without a formal consultation of the auspices. The augur, by his report of the omen being unfavourable, had it in his power to delay the meeting, or, on pretence of some informality in the necessary solemnities, could dissolve the assembly in any stage of its proceedings.

AUSTERLITZ, a small town of Moravia in Germany, to which the sanguinary conflict between the French and allied Russians and Austrians, on the 2d of December 1805, has given great celebrity. On that eventful day, the Russians lost 15,000 men in killed and wounded, and 100 pieces of cannon. The French, in whose favour the fate of war decided the engagement, have called it the battle of the *Coronation*, because it was fought on the anniversary of Bonaparte's coronation; while the presence of three emperors on the field has suggested to others the seemingly more appropriate designation of the battle of *the three Emperors*.

AUSTIL, or AUSTEL, a thriving town of Cornwall in England, contains nearly 4000 inhabitants, who are employed in the tin mines in the vicinity, in the manufacture of coarse woollen stuffs, and in the pilchard fishery, is the seat of a stannary court; and the porcelain clay, which is dug out from quarries in the neighbourhood, is transported to the potteries in different parts of England.

AUSTRALASIA, or SOUTHERN ASIA, a division of the globe first proposed by M. de Brosses, and adopted by succeeding geographers, comprehends all that space included between the 3d degree of north latitude and the 50th degree of south latitude, and between the 95th and the 135th degrees of east longitude. Within the defined limits are placed the vast island, or rather continent, of New Holland; Van Diemen's Land; Papua, or New Guinea; New Britain, New Ireland, and other islands in the same group; Solomon's Islands, or the Arsacides; New Hebrides, New Caledonia, and New Zealand; of each of which a description will be found under its own name in the order of the alphabet.

AUSTRIA, a province or archduchy of Germany, is bounded on the north by Bohemia and Moravia, on the east by Hungary, on the south by Styria, and on the west by Bavaria. At its utmost length it extends to nearly 190 British miles, and its medium breadth is about 80; and holds a central situation between the European capitals, Petersburgh, Constantinople, Madrid, and London. Austria is divided into Upper and Lower. Upper Austria occupies the west side of the Ens, and Lower Austria lies on the east side of that river.

Austria.

General aspect.—The outline of Austria resembles that of an open book. The Danube occupies the middle space, and rolls his waters through the whole length of the province. The banks, on either side, rise by a gentle ascent till the sloping surface meets the mountains. Lakes and rivers, woods and wilds, pastures and meadows, cultivated fields and flourishing vineyards, enrich and diversify the landscape; and cities, towns, monasteries, villas, and farm-houses, adorn the scene.

Mountains.—As a noble river passes through this country in the centre, so also mountain groups guard its frontiers. Upper Austria may be denominated a hilly country. The northern, and still more the southern boundary, rises to a mountainous elevation, of which the loftiest summits are, Priel, 6565 feet above the level of the sea, Œtscher 5900, and Hassberg 5215. Schneeberg, or *Snowy mountain*, attracts the attention of every stranger that visits Vienna.

Lakes.—Here, as in other mountainous districts, water stagnates in the pent up vallies, which in Upper Austria form an assemblage of beautiful lakes. Of these the Traun, the Wolf-gang, the Aber, and the Hallstatter, are most considerable for extent of surface and beauty of scenery.

Rivers.—The Danube (the Ister of the ancients), is not only the noblest of Austrian, but of European streams. It rises among the mountains of Swabia, and, passing many stately towns, flows with a majestic current through Bavaria, Austria, Hungary, and European Turkey, when, after a course of more than 1500 miles, it falls, by many mouths, into the Euxine sea, and mingles its streams with the waters of the world. All the other rivers of Austria tend toward and join the Danube. The Ens, flowing from the south, forms the line of separation between Upper and Lower Austria. The Styer, the Ips, the Traun, and the Trasen, flow in the same direction, and are remarkable for the greenness of their waters, arising from the colour of the sand which they hold in suspension.

Climate.—Like other regions of diversified and elevated surface, the temperature of Austria is subject to much variety. On the banks of the Danube the heat, in summer, is occasionally excessive, while, during a great part of the year, snow capes the mountains. The mean temperature of the springs is from 47° to 50° of Fahrenheit. In the upper districts the weather is inconstant and variable; transitions from heat to cold, and from cold to heat, are sudden and severe; and premature frosts, high winds, and heavy rains, frequently blast the hopes of the husbandman, and induce chronic complaints among the inhabitants. But the climate of Austria is, on the whole, favourable both for vegetation and health.

Soil and Produce.—The soil of Austria is composed either of deep alluvial deposites, or accumulations of gravel from the mountains. Among the mineral productions of Austria may be mentioned gold, which has been found in the vicinity of Krems, and silver in the mountains towards Styria. The salt of Upper Austria is a copious source of riches and revenue. The hot springs of Baden are well known; and with regard to vegetable productions, this country abounds with all those European plants which require a lofty or a low, a cold or a warm, an exposed or a sheltered situation, or which thrive in a rich or a poor, a moist or an arid soil. It is more fertile in corn and wine than most of the other German provinces. Its tobacco yields a considerable revenue; its saffron has long been esteemed the best in the world; and its mountain slopes are clothed with forest trees of great variety, and of an excellent quality. The animals of Austria,—its horses, cattle, sheep, goats, game, and poultry,—are numerous, and all deemed excellent according to their kinds. Its rivers, too, teem with numerous species of fishes.

Population.—The population of this province exceeds 1,500,000. Of this number more than 17,000 are foreigners, attracted to the schools and court of Vienna, or to the manufactories of the country. The nobility amount to nearly 4000, and the clergy to upwards of 4500.

Cities.—Besides a numerous and respectable peasantry, the population of this province is distributed among a multitude of cities, towns, and villages. Vienna, the metropolis of all Germany, and the residence of the imperial court, contains in the city and suburbs 256,000 inhabitants. Lintz, the capital of Upper Austria, has a population of 17,000 souls. The other considerable towns are, Krems, with 7000 inhabitants, Wiener Neustadt 5000, Waidhofen 4000, Kloster Neuburg 3000, Ens 4000, Freystadt 4000, Gmunden 3000, Wells 3000, together with many more of inferior note.

Agriculture.—Considerable attention is paid to the cultivation of this fertile region. The old system of management prevails; but an approximation is made to a regular rotation of white and green crops. The fields are secured against the irruption of rivers. The sloping surface of the country lays the cultivator under little necessity to study the principles, or to practice the art of draining. Irrigation is employed with success, and marl is used as a manure. Wine is the principal produce of Lower Austria. It is overspread with vineyards, from the grapes of which a wine of an acid taste, but of a wholesome quality, is prepared

Manufactures.—Austria has some claim to the appellation of a manufacturing country. Fabrics of woollen, silk, and cotton, are formed in its several towns. Vienna has many manufactories, for leather, paper, porcelain, glass, iron, steel, &c. for household furniture, toys, &c. The woollen manufactures of Lintz and its vicinity afford employment to more than 10,000 workmen. The preparation of salt gives scope to the industry of the inhabitants of Gmunden and some of the other towns of Upper Austria.

Religion.—The Roman catholic religion is established and prevails throughout the province. Toleration however is, under the sanction of law, extended to every other species of religious profession. The crown is patron of the church. The archbishop of Vienna is head of the clergy. The maintenance of the church is expensive. Under the influence of this corrupted Christianity, ignorance is deep and general, and the improvement of the human mind sadly retarded.

Government.—The emperor in this hereditary domain is almost absolute. In him the legislative and

Austria.

the executive power resides. He is the supreme judge and the source of honour. It belongs to him to impose taxes, to regulate the affairs of the church, and even to modify religious worship. Maria Theresa divided the executive government into four departments, —for domestic, foreign, and military affairs, and for the affairs of Hungary in particular. The whole jurisprudence of the country has lately undergone a complete revisal. The criminal code, in its amended form, was introduced into practice in 1804; and that for the regulation of civil matters was finally adopted in 1812.

Army.—Though Austria be a great military power, little is known with certainty respecting the actual state of her army. Recruits are first levied for the militia (landwehr), and thence the regular regiments are formed or filled up. A regiment consists of two field battalions, a battalion of reserve, and about 200 grenadiers, upwards in all of 3000 men. The active and hardy habits of the Austrian fit him for bearing the fatigues, the privations, and the dangers of the camp and of the field. There are public establishments for the instruction of the young officer; and the hospital of Vienna affords an asylum to the wounded and worn-out veteran. The time of service is limited as in the British army.

Revenue.—The resources for the exigencies of the state arise from heavy and numerous imposts. The imperial domains are said to yield an annual revenue of about L.100,000 Sterling. Taxes are levied on land, houses, mines, minerals, salt, tobacco, wine, &c. &c. also on places, pensions, postage, lottery-tickets, stamps, &c. Austria, like other European states, is deeply involved in debt,—not less, according to the latest information, than 150 millions Sterling.

Austria, house of.—The imperial family of Germany owes its origin to an illustrious founder. Rodolph, the first of this line, while count of Hapsbourg, was eminent for mental capacity and manly accomplishments, for justice, generosity, and humanity. His father's last advice was well fitted both to excite the love, and to direct the pursuit of honourable distinction. Actuated by the enthusiasm of the times, he had embarked in the crusades; and, previous to his departure to Palestine, he summoned his sons into his presence, and admonished them to remember, that the counts of Hapsbourg, their ancestors, had attained their greatness, not by violence and outrage, but by wisdom and courage, exerted in the cause of their country. He died in Syria; Rodolph succeeded to his honours; and in 1245, he married Anne of Hohenburg, who brought him some domains in Alsace. In those days of incessant appeals to the sword, Rodolph was obliged to be much in arms; his wars were waged, not for aggression, but for expelling hordes of banditti who infested the country, for humbling the nobles, who delighted to domineer over the industrious citizens, and for checking the ambition of the church, which the prelates disguised under the mask of religion.

While thus actively employed, he was astonished with the intelligence that he was unanimously elected king of the Romans. This happened in 1273, in the 55th year of his age. On his accession to the throne, it soon became conspicuous, from the elevation of his mind, and from the wisdom as well as the splendour of his actions, how well he was fitted to sway a sceptre. His first care was to conciliate the church; and he had the address to attach the pontiffs in succession to his interests. He adjusted intestine quarrels, and enacted wise laws; and then prepared to chastise the audacity of Ottocar, who having himself expected the imperial crown, had, in the paroxysm of his disappointment, loaded his rival with every species of insult. This powerful antagonist was soon obliged to sue for peace, which he purchased by renouncing his claims to Austria and the adjacent provinces, and by doing homage for the possessions he was permitted to retain. After this successful war, Rodolph entered Vienna in triumph, and was received with acclamation. A violation of the conditions of peace, however, which the proud spirit of Ottocar had acceded to with reluctance, soon provoked a renewal of hostilities. The adverse armies marched and met, and engaged in cruel conflict. In this bloody battle Ottocar was slain with 14,000 of his followers, among whom were many illustrious names. From this time Rodolph incorporated Austria with his hereditary domains, and spent the latter years of his life in peace, though not in idleness. His demise is dated in 1291. When (to employ the words of Mr Coxe) "we consider the greatness of his actions, and the smallness of his means; his extreme prudence and address; his ardour for military glory, yet his propensity to peace; his firmness in distress, and what is far more difficult, his moderation in prosperity; his shining talents as a sovereign, and his amiable qualities as a man,—we must place Rodolph among the best and greatest princes who ever filled a throne."

The same policy which had opened to Rodolph an access to the throne, operated against the succession of his son. During the preceding century the majority of the German electors had imagined, that to preserve their freedom entire they should never suffer the imperial power to reside, or to descend in the same family. Acting on this absurd principle they cherished among themselves the evil genius of discord; through whose influence Albert, the sole surviving son of Rodolph was superseded by Adolphus count of Nassau. But having at last triumphed over his rival, he obtained possession of the throne, which the hand of an assassin permitted him not to enjoy. After this tragical event the house of Austria sunk, and for a long series of ages continued in a private capacity. But the stock was fresh in the earth, and sent forth many a stately branch; though its ramifications were too numerous to command strength to repel the storms by which it was assaulted. More than a century had elapsed from the demise of Albert I. when his descendant, of the same name, was in 1437 chosen king of the Romans. After a short reign he was succeeded by his cousin Frederick, who experienced many vicissitudes of fortune; who, after many exiles and much wandering, saw before his death the re-union of the hereditary dominions of his house; and, by means of three successive marriages, the house of Austria, recently so low, became by the accession of Burgundy, Spain, Hungary, and Bohemia, the most powerful in Europe. To every reader of history, the names and mighty transactions of

Maximilian, Charles V. and their successors, are familiar.

On the death of Charles VI. in 1740, the family of Rodolph the Great became extinct in the male line. He left an only daughter, the far-famed Maria Theresa, espoused to Joseph, duke of Lorraine. This young and beautiful princess was at first involved in the most trying circumstances. On her accession to the hereditary crown of Hungary, she found an exhausted treasury, a disaffected people, inefficient councils, and powerful foes in league against her; yet with all the timidity, the softness, and delicacy natural to her sex, she yielded not up herself a victim to despair, but roused the energies of her mind to sustain the exigencies of her fortune, and saved her country by her courage. The king of Prussia had occupied Silesia, and threatened greater aggressions. In this extremity, the queen of Hungary convoked at Presberg the states of the kingdom, and presented herself before them, invested with the antique crown of the country, and the tattered robe of St Stephen. "The existence, (she said in Latin,) of our kingdom, of our person, of our children, and of our crown, is now at stake. Abandoned by all besides, we place our whole resources in the fidelity and valour of our long-tried Hungarians." This appeal of beauty in distress was not made in vain. With their hands on their swords, the deputies exclaimed, "we will consecrate our arms, our lives,—we will die for our sovereign Maria Theresa." A liberal supply of men and money was voted: Troops were collected from all quarters: Vienna was put in a state of defence; and the burghers and the students vied with the garrison to make a desperate resistance. By these means promptly applied, and the intervention of jealous feelings among her enemies, Austria was saved. After a long and a tumultuous life, Maria Theresa expired in 1780.

Long before this event, her son Joseph II. had been proclaimed king of the Romans. And, on his father Joseph of Lorraine's decease, he obtained the title of Emperor. Joseph II. was a man of a restless and an innovating disposition. These defects of his character his mother observed with regret, and sought to correct. He introduced many changes, some of which had a beneficial tendency, but most of them were eminently pernicious.

Leaving no child, he was, on his death in 1790, succeeded by his brother Leopold II. who was soon involved in the French revolutionary war. On his decease in 1792, his son, Francis II., succeeded to the crown, which he still wears. A better opportunity than the present will occur to introduce the details of the Bonapartian wars, in which the house of Austria was so deeply concerned. But it may be noticed, that Francis, overwhelmed by his enemy, relinquished, in 1804, the title of emperor of Germany, and became a vassal of France; that in 1810 he sacrificed his eldest daughter Maria Louisa to pacify his conqueror; and that in 1815 his capital became the scene of those arrangements which have given tranquillity to Europe, and restored him to his honours and influence.

AUTOMATON, from the Greek, and signifying to *move itself*, is a self-moving machine; but the term is usually limited to those machines which imitate the actions of animals, and even of man himself. When the automaton, or self-moving machine, is in the human form, it is called *Androides*, which denotes the *resemblance of man*. Mechanical ingenuity has been industriously employed in all ages, in the construction of machines of this description. If full credit can be given to the relations of authors, the ancients were not deficient in this application of mechanical skill. Dædalus constructed statues, which, it is said by Aristotle, moved about by means of quicksilver; and Archytas of Tarentum, who lived 400 years before the Christian era, contrived and executed a wooden pigeon, which could raise itself in the air; Friar Bacon, who lived in the 13th century, formed a brazen figure which imitated human speech; Albertus Magnus, who flourished about the same period, occupied 30 years of his life in the construction of an artificial man: And John Muller of Nuremberg, better known by the name of Regiomontanus, made a wooden eagle, which took a flight through the air, saluted the emperor Maximilian as he approached Nuremberg, and having returned, waited his arrival at the city gates. But some of these accounts are too much veiled in fable, and others are too vague and exaggerated to afford precise information. Of the numerous specimens of extraordinary mechanism which the ingenuity of modern times has furnished, a few may be specified.

The Flute-player.—In the year 1736, M. Vaucanson, member of the royal academy of Sciences, exhibited at Paris an Androides, which played several airs on the German flute. The machine was composed of a figure five and a half feet in height, seated on a fragment of rock, which was supported by a pedestal four and a half feet high by three and a half feet broad. When the front of the pedestal was opened, the clock-work was seen, by the operation of which a steel axis was put in motion. To various protuberances on this axis, were attached cords, which being passed over pullies, terminated in the upper boards of nine pairs of bellows, which, by the revolution of the axis, were alternately elevated and depressed. The valves were opened by levers, which produced a uniform unbroken sound. The air discharged by the nine pairs of bellows was received into three tubes, which conveyed it to three small reservoirs placed in the trunk. Here the tubes were united into one, which was continued to the throat, and formed the cavity of the mouth. Three pairs of bellows were attached to each of the three pipes. The upper boards of one set were depressed with a weight equal to four pounds; those of the second set, with a weight equal to two pounds; and those of the third with their own weight. In this way the air was furnished to the machine.

By means of another series of machinery, the requisite movements were communicated to the lips, the tongue, and the fingers. All this was effected by the revolutions of a cylinder, in which brass pegs were inserted for raising and depressing fifteen levers, seven of which, through the intervention of steel chains and pullies in the body and arms of the figure, regulated the action of the fingers in opening and shutting the holes of the flute; three levers which

Automaton. were connected with the valves of the three small reservoirs, were employed in regulating the current of air for the modification of the tone; four of the levers acted upon the mouth in the same way, and gave the proper motions to the lips, and the last lever moved the tongue, by which the mouth of the flute was shut and opened. By means of an endless screw, which terminated the axis of the cylinder, a new series of revolutions was communicated to the levers, during twelve different revolutions. The screw consisted of twelve threads, placed at the distance of a line and a half from each other. Above the screw was fixed a piece of copper, in which a steel pivot was inserted; and this pivot, working in the threads, produced a change of position in the cylinder, during every revolution of the axis, and thus brought into action different pegs on different levers. By an artificial disposition of the pegs on different parts of the cylinder, the statue was made, by the successive elevation of the different levers, to exhibit all the requisite variety of motions in a flute-player.

To give a single example, let it be supposed that the lowest note of the flute, D, is to be sounded,—this is effected by closing all the holes of the instrument with the fingers, and by gently blowing into it a full body of air. To give the mouth the proper form, a peg is fixed in the cylinder under the lever, which is destined to enlarge the lips; another peg is placed under the lever which draws back the lips; another under the lever for opening the valve of the reservoir which communicates with the unloaded pair of bellows; and lastly, a peg is inserted under the lever, which regulates the motions of the tongue, for the purpose of giving the proper articulation to the note. If all these pegs operate on their proper levers at the same moment, the sound required must obviously be produced. By raising the third finger of the right hand, and opening the sixth hole of the flute, and continuing the former motions, the note E, which is next in the scale, is sounded. Here a fifth motion is added, which is done by inserting a peg in the cylinder under the lever which acts on the third finger of the right hand. Proceeding in this way, all the notes of the first or lowest octave are sounded. To produce the notes of the second octave a change must be made on the mouth, and the air must be forced out with greater velocity. This is effected by opening the reservoir, which is supplied by the pair of bellows loaded with two pounds; and in the third octave another change must take place on the mouth, and the air is conveyed with still greater velocity from the reservoir to which the bellows loaded with four pounds are attached.

M. Vaucanson, in the year 1741, exhibited to the royal academy of Sciences another musical Androides, in the form of a shepherd, which performed about twenty different tunes on the pipe and tabor. The flageolet was held in one hand, and to produce the highest tone of the instrument the bellows required to be loaded with a weight equal to 56 pounds, while a single ounce was sufficient for the lowest note. The other hand held a stick for beating the tabor. Sometimes the strokes were single, sometimes double, and sometimes a rolling noise was produced. This automaton was regarded as a very extraordinary effort of mechanical skill and execution.

Chess-player.—A still more wonderful piece of mechanism was constructed and exhibited to the public in different parts of Europe, by M. Kempelen, a gentleman of Presburg, in Hungary, in a figure of the size of life, which not only played the complicated game of chess, but it is said usually beat even the best players. This figure was exhibited in Britain in 1783 and 1784, and excited no small degree of astonishment in those who had an opportunity of witnessing its extraordinary performance. It was dressed in a Turkish habit, and seated on a chair behind a table with doors. The chair was connected with the table. The whole apparatus was moved about the apartment on four wheels. By inspecting the table and the body of the Androides, nothing appeared but wheels, cylinders, and levers; after this examination was finished by the spectators, the game commenced by the automaton taking the first move; at every movement the machinery was heard, which was accompanied with a motion of the head, as if the figure cast its eyes over the board to consider the state of the game. When a false move was made it shook its head; in checking the queen it shook the head twice, and three times to the king. After every ten or twelve moves the machine was wound up like a watch, and the inventor, or his assistant, was always at hand, and frequently consulted a small square box, in which it was said the whole secret lay. The directing power of this machine was long altogether inexplicable. But it was at last ascribed to the operation of a well-taught boy, so thin and small of his age that he could be concealed in a drawer under the chess-board; or to a dwarf, an expert chess-player, who was kept out of view, by changing his place during the examination of the apparatus previously to the commencement of the game. These allegations were made in two publications concerning Kempelen's chess-playing Androides, one of which appeared in Germany, and the other in Paris in 1785; and the movements of the adversary were supposed to be observed through a transparent chess-board, or were indicated by levers or some pantographical contrivance. See AUTOMATON in *Supplement* to Hutton's *Mathemat. Dict.*

Speaking Androides.—The same ingenious person made the bolder attempt of constructing a machine capable of imitating human speech. While M. Kempelen visited London with his chess-player, he exhibited this machine in an unfinished state; but it is said that he could make it pronounce any word that was mentioned by those who were present. According to all accounts, the imitation was extremely imperfect, both with regard to the individual sounds, and the rapid succession necessary, even in a distant approach to the resemblance of the wonderful variety and extraordinary execution of the human voice. It was assuredly far inferior to the harsh and discordant speech of the deaf and dumb, in whom the organs are perfect, but the power of modulation is deficient. The defects of the mechanical contrivance extend to the construction and nice adaptation of the different parts, as well as to the imitative expression.

Rope-dancers, &c.—Figures which imitate all the motions of rope dancers, have been constructed and exhibited in this country, chiefly by ingenious foreigners. An Androides of this description, as large as life, formed part of an entertainment with which M. Philipstahl amused the inhabitants of many of the towns of Great Britain about the year 1801, or 1802. Among many examples of great mechanical ingenuity exhibited about 1804 and 1805, in different parts of this country, by M. Maillardet, a native of Switzerland, one figure as a boy wrote several lines with neatness and accuracy, and sketched three beautiful landscapes; another figure in a female habit performed pieces of music on an instrument which acts as an organ, but is constructed like a piano-forte, the bellows being blown by some part of the machinery, and the whole of this complicated apparatus being set in motion by six powerful springs; and a small figure, in the character of a conjuror or magician, who gives appropriate answers to questions inscribed on medallions, which are put into a drawer, and the drawer being shut the magician solemnly rises from his seat, consults a book which he holds in one hand, and waves a wand in the other, when a pair of folding doors fly open, and the answer appears.

A description is given by M. Camus of a very curious piece of mechanism, which he invented and constructed for the amusement of the celebrated Louis XIV. of France, when a child. A small coach, in which was seated a lady, was drawn by two horses, and attended by a footman and page, who stood behind it. The coach was placed on a table, the coachman smacked his whip, the horses moved their legs, and when the carriage, after proceeding along the edge of the table, and turning at the angles, reached the place near which the king sat, the page jumped down and opened the door, the lady alighted, curtsied to the king, and presented a petition; and having waited a little, curtsied again, and resumed her place in the coach, which afterwards moved off. Ozanam's *Mathemat. Recreations*, by Montucla.

M. Vaucanson, the inventor of the flute-player, constructed an artificial duck, which not only imitated the different motions of the animal in a very exact and natural manner, but *seemed* also to have the power of digesting the food which it swallowed; from which it is to be understood, that by some contrivance, whether by mechanical mixture or chemical action with other substances previously introduced within its body is not known, it had changed its appearance. M. Maillardet constructed a spider, which ran round a table for two or three minutes; and one of the most curious productions of the same ingenious artist, was a box about the size of an ordinary snuff-box. The machinery in this apparatus was put in motion by springs; and when wound up, and the box was placed on the table, the lid opened, a bird with the beautiful plumage of the humming-bird, and not larger, sprung up from its nest, fluttered its wings, began to warble with tremulous notes, and continued to sing for some time, when it darted again into its nest, and the lid closed after it.

AUTUMN, the third season of the year, is represented in painting under the figure of a man of full age, bound round the middle with a starry girdle, and having in one hand a balance, with a pair of scales, in each of which is placed a globe, and holding in the other a bunch of grapes and various other fruits. The progress of the season is indicated by his perfect age and the collection of fruits; and the balance denotes the sign of the zodiac which the sun enters at the commencement of autumn.

AUTUN, a town in the department of Saone and Loire in France, can still boast of some remains of Roman antiquity, in the ruins of temples, a theatre, and other buildings; contains a population of 9000; and from the surrounding country supplies Paris with large quantities of wood for fuel and other domestic purposes. Coal and iron ore are dug out in the vicinity; and the town derives an abundant supply of water from the springs which have their source in the mountains at the foot of which it is situated.

AUVERGNE, a former province of France, is included, according to the new division, under the departments of Cantal and Puy de Dome.

AUXERRE, the capital of the department of Yonne in France, stands in a commodious situation on the declivity of a hill, and is surrounded with rich and beautiful scenery. The cathedral and the episcopal palace have been greatly admired for their magnificence. The population is estimated at 12,000. The trade in wines, some of which, as the Coulange and the Chablis, are in high repute, is considerable; and from this place Paris receives a large supply of timber, which is transported by water carriage on the Yonne and the Seine.

AUXONNE, a small fortified town in the department of Cote d' Or in France, is chiefly remarkable for its long bridge of 23 arches, and extended pavement or causeway, both which are necessary to obviate the inconveniences of inundations of the Saone, on whose banks it is situated; contains more than 5000 inhabitants, and has some trade in timber and corn.

AXIM, a district of the Gold Coast in Africa, was originally in possession of the French, who, in 1515, were expelled by the Portuguese; and the latter, in their turn, were dispossessed by the Dutch, who afterwards shared the territory with the Prussians. The soil is rich and fertile, and produces abundance of rice, millet, yams, palm oil, and excellent fruits. Black cattle, sheep, goats, and poultry, are successfully reared. Gold dust, ivory, and formerly slaves, with the manufacture of salt, and the building of canoes, are the chief objects of commercial industry, or afford occupation to the inhabitants.

AXIOM, a truth or proposition which requires no demonstration or train of reasoning to establish it, but is self-evident, or obvious to every person at first sight. Thus, *the whole is greater than a part*, is an axiom in geometry.

AXMINSTER, a small town of Devonshire in England, was a place of some note in the time of the Saxons, but is now chiefly distinguished for its manufactory of carpets, the fabric of which is an imitation of the celebrated Turkey carpets. Axminster contains a population of more than 2000, and it enjoys an excellent weekly market.

AXUM, or AXUMA, once a flourishing and populous city of Abyssinia, and the capital of the kingdom, till it was destroyed by the Turks about the beginning of the 16th century, is now only conspicuous for its magnificent ruins. Several obelisks of single blocks of granite, one of which reaches to the stupendous elevation of 80 feet, and even the smallest are 36 feet in height, yet remain, the striking monuments of its ancient splendour.

Axum is seated in a valley, of which the soil is rich and productive. The modern town contains about 600 houses. Coarse cotton cloth, and parchment made from goats skins, are the chief manufactures.

AXYRIS, a genus of plants belonging to the Monoecia class.

AYENIA, a genus of plants belonging to the Pentandria class.

AYLESBURY, a very ancient town of Buckinghamshire in England, is finely situated in the rich vale of Aylesbury, was a place of some note even before the time of the Saxons, and was granted to William of Aylesbury by William the Conqueror, on the peculiar conditions of finding straw for the king's bed, and three eels for his table in winter; and straw for the bed, sweet herbs for the chamber, and three green geese for the table in summer; and this provision was to be made three times a year, if required. Aylesbury is the seat of the quarter sessions of the county and the Lent assizes; the number of inhabitants exceeds 3000; they are chiefly occupied in the manufacture of lace; and it is 17 miles from Buckingham, and 40 miles north-west from London.

AYR, a maritime county of Scotland, which has the frith of Clyde and the Irish channel as its boundary on the west, for an extent of between 70 and 80 miles from its northern limit, where it joins Renfrewshire, to its southern extremity, where it is united with Galloway. The counties of Lanark and Dumfries mark its confines on the east; and, in somewhat of a crescent form, the greatest breadth is estimated at 32 miles. The computed area is more than 1000 square miles; it is divided into three great districts,—Carrick, lying to the southward of the river Doon; Kyle, occupying the intermediate space between the Doon and the Irvine; and Cunningham, which comprehends the northern portion. The Great and Little Cumbray, and the rock of Ailsa, are also included in the county.

General aspect.—In its general appearance, Ayrshire presents considerable variety. In several places extensive flats stretch along the shores; in others a gently undulating surface is the chief feature; and towards the interior, and in the southern district, it is to be regarded rather as a hilly country than rising into a mountainous elevation. The sand-floods have left some dreary wastes along the shores of Ayrshire; and it would appear that, in certain instances, the date of this calamitous visitation is not very ancient. An old map still in existence represents the extensive tract of sand-hills between Saltcoats and Irvine, covered with arable land, and studded with farm-houses.

Rivers, &c.—The rivers of this county are the Ayr and the Doon, to which the muse of Burns, their native bard, has added classic celebrity, the Garnock, the Irvine, the Girvan, the Stinchar, and their tributary streams. The banks of the chief rivers present numerous beautiful and picturesque scenes; and they are adorned with many elegant mansions, the family residences of the great proprietors. Loch Doon, which is seven miles long, and is the source of the river of the same name, and Kilbirnie loch, near Beith, in the northern district, are the principal lakes. The waters of Ayrshire abound with fish; and where the larger rivers discharge their waters into the ocean, fisheries of salmon are successfully conducted. The white fisheries along the shores are also profitable sources of employment.

Natural history.—Ayrshire abounds in some places with coal. Extensive tracts of that valuable mineral are deposited in the vicinity of Saltcoats, Irvine, Kilmarnock, and Ayr, from which large quantities have been long dug out, not only for home consumption, but for exportation to Ireland. The vale of Girvan, in the district of Carrick, affords also an ample supply of coal to the surrounding country for domestic and agricultural purposes; and repositories of the same mineral, of less limited extent, are numerous in the interior of the county. Limestone is not less abundant, although it be found economical to import it sometimes from the north of Ireland as ballast or as a return cargo. The sandstone in Kyle and Cunningham is of an excellent quality for building, and it is sometimes exported to Ireland. The iron-works of Muirkirk and Glenbuck are supplied with all the necessary materials of their manufactory. Lead ore is not to be considered a copious production, but attempts have been made to work it in a few places; and Ayrshire can boast of the only mine of the rare mineral *plumbago*, or black lead, excepting that of Borrowdale, in Britain. The *Water of Ayr stone*, a whetstone of an argillaceous quality, much valued by carpenters for their edge-tools, is dug out from a single spot on the banks of the river from which it derives its name.

The prevailing rocks in the southern district of Ayrshire are grey wacken of modern mineralogists, and when the same rock assumes a schistose or slaty structure it is applied to the purposes of roof slate; secondary limestone, of which considerable masses appear, and are extensively wrought for the improvement of the soil; and red sandstone, which is visible in a few places along the shore. Brown Carrick hill, near Ayr, is composed of porphyry, which affords indications of lead ore. In the middle district, beside the coal strata, an extensive tract of red sandstone traverses the interior, and runs from north to south; and the same rock commences near Saltcoats, and continues along the shore beyond the northern limit of the county.

Botany.—The Flora of Ayrshire includes some plants which may be accounted rare in Scotland, or are chiefly confined to the western districts. The lover of botany, whose excursions shall be directed that way, may be gratified in knowing where to find them in their native soil. *Pulmonaria maritima*, sea-bugloss, reckoned one of the most beautiful indigenous plants of Great Britain, occasionally springs up, the solitary ornament of the barren shores of Kilbride, and with its finely undulated azure leaves, contrasted with red and blue flowers, diversifies the arid scene. *Samolus valerandi*, water pimpernel, grows on the sea-marsh between Hunterston and the sea. *Sison verticillatum* (*Sium verticil.* of Dr. Smith), whorled water parsnip, in moist pastures in Kilbirnie parish. *Lysimachia Thyrsiflora*, tufted loosestrife, a very rare plant in Britain, which we were fortunate in discovering several years ago in Ashgrove loch, two miles north-east from the village of Stevenston. *Rosa cinnamomea*, cinnamon rose, on the east bank of the Garnock, above Kilwinning. *Nymphea lutea*, yellow water lily, in Ashgrove loch. *Iberis nudicaulis*, rock cresses, on sandy pastures near the old coal-pits of Misk, on the banks of the Garnock. *Sisymbrium monense*, Isle of Man rocket, clothes the pastures or downs along the whole coast of Ayrshire with its elegant pinnated leaves and yellow flowers. *Sisymbrium amphibium*, jagged water rocket, in some of the old canals at Stevenston coal-work. *Hypericum Androsæmum*, tutsan or parkleaves, one of the most splendid native plants, adorns the woods of Lord Glasgow's seat of Kelburn. *Solidago lanceolata*, spear-leaved golden-rod, which we observed, in 1814, in great profusion on an old coal-hill on the north side of the road between Maybole and Girvan, and nearly opposite to Kilkerran, the seat of Sir James Ferguson. *Osmunda lunaria*, moon-wort, on the sandy downs between the village of Stevenston and the sea. *Osmunda regalis*, royal flowering fern, displays its elegant leaves, and conspicuous flowering stem, from the crevices of the rocks of an old quarry, close by the house of Ardeer, near the same village; and *Equisetum hyemale*, Dutch rushes, grows on places where the water stagnates in winter, at the head of the Newton-green, near Ayr.

Population, towns, &c—The population of Ayrshire, within the period of little more than half a century from 1755, has nearly doubled. In 1755 the number of inhabitants was estimated at 59,268; in 1801 at 84,306; and in 1811 at 103,954. The real rent of lands and houses in 1811 amounted to L.359,294 Sterling. The county is divided into forty-nine parishes. The chief towns are Ayr, the capital of the county, and Irvine, both royal boroughs and sea ports; Saltcoats, Ardrossan, and Troon, also sea ports; Girvan and Ballantrae, which admit small vessels into their harbours; Kilmarnock, which has been long famous for manufactures of woollen stuffs, chiefly carpets, and of leather; Maybole, Cumnock, Mauchline, Catrine, Beith, and Kilwinning. The new town and harbour of Ardrossan, begun under the auspices of the Earl of Eglinton, when completed, will be highly advantageous to the trade of that coast; its fine situation, and excellent baths, render it a commodious and delightful watering place. Troon, on an intermediate spot between Irvine and Ayr, affords a similar example of patriotic spirit, in the splendid operations of forming a harbour, building a town, and constructing a railway ten miles in length, for the purpose of easy communication with Kilmarnock and its populous vicinity, which have been undertaken and executed by the duke of Portland. A single horse used to draw three tons ascending, but favoured by the declivity towards the shore, five tons weight; and 100 tons of coals have been shipped in a day by this railway. The new application of the steam-engine is now adopted as the moving power to the carriages. Catrine, which numbers 3000 inhabitants, dates its origin and remarkable increase to the introduction and establishment of the cotton manufactory within the last thirty years. The power of water and of steam is successfully employed in the spinning and weaving of cotton.

Husbandry.—Ayrshire, in general, has been supposed to be less advanced in agricultural improvements than some other districts of Scotland. But examples are not wanting of successful cultivation both among proprietors and tenants. The stiff clay soil in the interior districts, and the moist climate, render the crops late and precarious; but they are earlier and more certain on the light loamy soils on the plains near the shores. The hilly tracts of country afford excellent pasture to sheep and cattle. The management of the dairy has been long an object of successful attention in Ayrshire, and the superiority of Dunlop cheese is generally acknowledged. The improvement of peat-moss, which is one of the most important in modern agriculture, and has clothed many barren wastes with luxuriant crops or rich pastures, was first suggested by Mr Smith of Swincridgemuir in this county.

Trade.—The commercial intercourse of Ayrshire extends to Ireland, America, and the Baltic. Coals, to the amount of 100,000 tons, have been exported in one year to Ireland. Beside the coasting trade, the imports are, Irish produce, as grain, butter, and beef; hemp, iron, and timber from the Baltic; and timber from America.

Antiquities.—Numerous remains of ancient baronial residences are seen in Ayrshire. The abbacies of Crossraguel and Kilwinning were richly endowed; the territory which they held constitutes a valuable part of the possessions of the lay proprietors who had the power or influence to come in for a share on their suppression; and the mouldering ruins of the first still attest its former splendour. The Lazar-house, known by the name of *King case*, perhaps from *casa*, "cottage," or *Killcase*, signifying "the cell of the cottage," is a peculiar institution in the parish of Priestwick, two miles from Ayr, which was destined for the reception and maintenance of eight persons afflicted with leprosy. Lame and infirm persons have long enjoyed the benefits of the charity, which consist of a portion of meal, butter, &c. from certain lands in Carrick, the patrimonial domain of the royal founder. The right of presenting to this charity formerly belonged to the Wallaces of Craigie. The ruins of Alloway church, three miles from Ayr, would scarcely merit notice among the antiquities of the county, had they not been destined to future fame in one of Burns's finest productions, in which the legendary lore of the country is artfully embodied, and the versatile powers of the poet are finely displayed, in the exact delineation of human character, in sublime and terrific description, and in the expression of comic humour, delicate satire, and pathetic feeling.

AYR, town of, the capital of the county of the same name, stands on the southern bank of the river Ayr, and near its junction with the sea, is a place of considerable antiquity, as appears from its charter, granted about the end of the 12th century, and in former times was noted as a strong-hold. Oliver

Cromwell deemed it of such importance as to erect a regular citadel, defended by six bastions, part of which is still entire. Within its area the old church of St John the Baptist was included, and was converted into an armoury by the usurper, who granted 1000 marks, or L.666, 13s. 4d. for building another church. The tower of the old church only remains, and is a conspicuous landmark to the mariner in approaching the shore. The streets are not very regular, but some are spacious and airy; and houses lately erected are commodious and elegant. An academy, at which more than 500 pupils are ably instructed in the knowledge of languages, and in various practical branches of education, was established in 1790, and continues to flourish.

In 1801 the population was estimated at 5492, but in 1811 it had increased to 6291. They are employed in tanning, soap-making, weaving, ship-building, and in trading to Ireland, the Baltic, and America. Shipping, to the amount of 5000 or 6000 tons, belongs to the port; and 50,000 tons of coal are annually exported to Ireland.

Connected with Ayr, by means of two bridges, which are commemorated in the poetry of Burns, and seemingly forming part of the town, are Newton-upon-Ayr and Wallacetown; the first an ancient borough of regality, held by a singular tenure, now a distinct parish, and containing nearly 2000 inhabitants, who are chiefly occupied in fishing, rope-making, and weaving; and the last a modern village, included in a country parish.

The Chevalier Ramsay, the celebrated author of the *Travels of Cyrus*, was a native of the town of Ayr; and few readers need be informed that Robert Burns was born in a clay-built cottage in the annexed parish of Alloway. Ayr is 34 miles distant from Glasgow, and 76 miles from Edinburgh.

AZALEA, American upright honeysuckle, a genus of plants belonging to the Pentandria class.

AZIMUTH, a term in astronomy, applied to an arch of the horizon intercepted between the meridian of the place and the vertical circle, passing through a star or other body in the heavens, whose azimuth is to be determined. See Astronomy, p. 497.

AZOF, a town of Cuban Tartary, under the dominion of Russia, stands near the mouth of the Don, and has been subject, at different periods of its history, to the Genoese, Turks, and its present masters. The population is estimated at nearly 4000; but the inconvenience of the harbour, which has been gradually filling up with sand, and other causes, have produced a decline of the trade.

AZOF, Sea of, an inland sea, forming part of the Russian empire, has a communication, by a narrow strait, with the Euxine sea, lies between the 45th and 47th degrees of north latitude, and between the 34th and 39th degrees of east longitude, and is about 200 miles long and 50 miles broad. Extensive and successful fisheries are established on the northern shores Taganrok is the chief harbour, and enjoys a valuable commercial intercourse with Natolia and the Crimea. During a severe shock of an earthquake, in September 1799, an island rose above the surface of its waters; and its emersion was accompanied with a loud noise, like the discharge of artillery, and with a copious eruption of smoke and flame. Pallas' *Travels.*

AZORES, or Western Isles, a cluster of nine islands, lying in the Atlantic ocean, between the 36th and 40th degrees of north latitude, and between the 25th and 33d degrees of west longitude, were originally discovered by the Flemings in 1439, and now acknowledge the authority of Portugal. The Azores enjoy a fine climate, and produce grain, excellent fruits, and a good deal of wine; but they are subject to severe storms, and to the more dreadful visitations of earthquakes and volcanoes.

St Michael,—which is the largest of the Azores, is about 80 miles long, and from 6 to 12 miles in breadth, and presents a varied surface of extensive plains, covered with excellent crops of wheat, barley, and Indian corn; conical hills, whose sides are clothed with vineyards and orange plantations; and lofty mountains, adorned with luxuriant evergreens, among which the laurel and myrtle are not the least conspicuous. The chief towns, Punta del Gada and Ribeira Grande, contain each about 12,000 inhabitants; and some of their churches and religious houses are elegant structures. The whole population is estimated at 90,000. Hot springs are numerous; and the boiling fountains and muddy crater, in a state of constant agitation, in the valley of Durmas, with the copious deposition of sulphur, are certain indications of volcanic activity. *St Mary,* contiguous to St Michael, is a small island, with a fertile soil, which produces wheat in such abundance as to afford a considerable exportation.

Tercera,—is smaller than St Michael, abounds in grain and cattle; Angra, which is the chief town and harbour, is the residence of the governor; the population is estimated at 50,000, and it exhibits fewer marks of volcanic agency than the other islands of the group. The wines of Tercera are considered of an inferior quality, and the fruits raised are not more than sufficient for the consumption of the inhabitants.

Fayal,—abounds with all kinds of fresh provisions, and on this account it is much frequented by ships navigating the Atlantic. Villa de Horta, the chief town, contains numerous churches, and several monasteries. The bay is spacious and commodious, and, excepting with south-east winds, is reckoned a safe roadstead.

Pico, or *the Peak,*—is a remarkable island, composed of a huge conical mountain, which rears its head to the immense elevation of 7000 feet, or nearly a mile and a half. The lower regions of the mountain are highly cultivated, and richly clothed with vineyards and orange plantations; and 5000 pipes of wine, of the nature of Madeira, are annually exported; and as it is shipped at Fayal, it is known by the name of Fayal wine.

St George and Graciosa,—are two small islands between Tercera and Fayal. Graciosa is chiefly remarkable for its fine scenery. St George is fertile in corn and fruits, and abounds in cattle; but in May 1808 it was visited with a most destructive volcanic eruption. This awful disaster commenced on the 1st of May, and, with some intermissions, continued till the 5th of June. The island was convulsed with

Azote.

earthquakes; vapour and flames were emitted, and enormous quantities of ashes and lava were ejected; overwhelming in their progress vineyards, corn-fields, farm-houses, and cattle; and many of the inhabitants, scalded with the hot steam, expired on the spot.

Corvo and Flores,—which complete the group of nine islands, lie at a considerable distance from the rest of the Azores. Some of the numerous bays of the latter island afford safe and commodious shelter to ships. Flores has been long celebrated for the excellence of its poultry; and its herds of a small kind of cattle are abundant.

AZOTE, or azotic gas, from the Greek, and signifying *destructive of life,* because it is unfit for the purpose of respiration when it is in a state of purity, is one of the constituents of the air of the atmosphere, in the proportion of 79 parts to 21 of oxygen gas. In the older books on chemistry, it is denominated *phlogisticated air*; and it is sometimes called *nitrogen,* because it is the base of nitrous gas and nitrous acid. See CHEMISTRY.

Azure.

AZURE, was formerly applied to the fine powder prepared from *lapis lazuli* for painting, and is now restricted to the preparation of the oxide of cobalt, combined with vitrifiable matters, in which state it is employed to colour glass and pottery-ware. See CHEMISTRY.

Baal || Babel.

Babelmandel || Babylon.

B.

B is the second letter of the English alphabet and of most others, is arranged with the letters called labial, because the lips are the chief organs in its pronunciation, and having a close affinity with P and V, the other labial letters, is substituted occasionally for both in ancient languages.

Among the Greeks and Hebrews the letter B was employed as a numeral, and denoted 2. When used as a Roman numeral, B signified 300, and with a line above it 3000. The letter B is frequently employed as an abbreviation, as, B.A. bachelor of arts; B.L. bachelor of laws; B.D. bachelor of divinity; and B.F. prefixed to decrees of the Roman senate, denotes *bonum factum*.

BAAL, or BEL, or BELUS, from the Hebrew, and signifying *lord* or *ruler*, was the god or chief object of worship among the Chaldeans, Phœnicians, and other eastern nations. Under this denomination the sun was worshipped; but it seems to have been extended to all the heavenly bodies, or, according to the language of sacred Scripture, *all the host of heaven;* and the temples and altars consecrated to this idolatrous worship were erected in high places. Perpetual fire was kept burning in them, which seems to have been intended as an expression of the permanency and uniformity of the heat of the sun, one of the chief objects of adoration. 2 Kings, chap. 23.

BABEL, a tower which was undertaken by the descendants of Noah; but their object was defeated by the miraculous introduction of the confusion of languages among those who were engaged in its execution. This tower was built in the plain of Shinar, and near the place where ancient Babylon afterwards stood. It was constructed of burnt bricks, cemented with slime or mud, instead of mortar, and the period when the undertaking commenced is variously stated at 105 years, 396 years, or 525 years after the flood. The dimensions of this famous tower, as they have been estimated by historians, are not less various. While some have ascribed to it the incredible height of four and even twelve miles, others have reduced it to about 700 feet; and a traveller, who examined its remains in 1779, asserts that its altitude is not less than 160 feet, and it appears like one uniform mass of earth.

Much speculation has been employed in discovering the object of this stupendous undertaking. From the scriptural expression of building a *tower, whose top may reach to heaven*, it has been inferred that the design of mankind in uniting their ingenuity and labour in this work, was literally to enable them to climb to heaven; but according to other opinions, it was intended as a place of retreat for safety, in case of a second deluge; or a monument or temple in honour of the sun, to whose influence the diminution of the waters of the flood, and the drying of the earth, was ascribed; or as a conspicous land-mark to direct their steps to their native city, after they spread over the country as their numbers increased. But it is quite obvious that all this is vague conjecture.

BABELMANDEL, or BABELMANDEB, a cape and straits at the entrance of the Red sea from the Indian ocean, sometimes called the *Straits of Mocha.* The breadth of the straits, by the latest observations, is not more than 15 miles. They are divided by the low, flat island of Perim, or Babelmandel. The cape is in N. Lat. 12° 40′, and E. Long. 43° 33′.

BABOON, the trivial name of a species of *simia.* See MAMMALIA.

BABYLON, a celebrated name in ancient history, and in the sacred Scriptures, is applied to a magnificent city, a powerful empire, or an extensive region. The name, signifying *confusion*, arose from the events recorded in Gen. ix. 1—9; for the city included the tower which the children of men had projected, and had begun to build, till their enterprise was frustrated by the confusion of their language.

City of Babylon.—Babylon was built in the vast plain interposed between the Euphrates and the Tigris. A branch of the former divided its area into two equal parts, which together formed an exact square, with sides 15 miles in length. The whole of this vast space was fortified by a stupendous wall 87 feet thick, and 350 high, which was encompassed by a ditch, brimful of water, of a corresponding magnitude, and surmounted at regular intervals by numerous turrets. Through these walls it communicated with the surrounding country by means of 100 brazen gates. The streets, in parallel lines, extended from gate to gate, and intersecting each other at right angles, divided the whole expanse into 676 squares, around which were built the houses, exhibiting ornamented fronts, and rising three or four stories in height. The intermediate spaces were employed as gardens, court-yards, and other accommodations. The river was lined with a noble quay, and crossed by a magnificent bridge; and for a defence against its annual inundations, prodigious banks, constructed with great art and infinite labour, increased its capacity; expansive artificial lakes drained off its superabundant waters, or broad and deep canals turned its streams into the Tigris. On the banks of the river, close by the bridge, stood the old and the new palaces; and in the vicinity of the first the temple of Belus,—the unfinished tower of Babel,—four furlongs in compass, and lifting its head to the clouds by eight steep stories, each exhibiting the appearance of a distinct tower. This appearance was occasioned by a passage which winded around from the ground to the summit, where was an excellent observatory. Edifices for the worship of Belus, and other idols, were ranged around

Babylon. its base. The hanging gardens, enumerated among the wonders of Babylon, were sustained by stupendous arches, and rose by regular recession, in a series of terraces, the respective areas of which were 400 feet square. A course of large stones, a layer of reeds and bitumen, and a covering of lead imposed upon the arches, prepared these squares for a deep bed of rich vegetable mould. In the front of the terraces, delightful apartments, commanding an extensive view, were formed; and water, raised from the river by machinery, distributed refreshing moisture to the richest variety of herbs, fruits, and flowers.

Building of Babylon.—The description of Babylon, seems to partake of the extravagance of an eastern tale, fitted indeed to regale the imagination, but to have little claim to the sobriety of historical truth. The erroneous estimate of ancient measures may have led to exaggeration; but, after every allowance, Babylon, in its ancient state, exhibits a grandeur not to be contemplated without astonishment. Dr Gillies takes the stadium at a length which circumscribes the city, and diminishes its walls; yet, even according to him, Babylon was eight times larger than London and its suburbs. The authority of Scripture also supports both the antiquity and the greatness of this celebrated city. The trespass, so fatal to Achan, and so calamitous to Israel, originated in his desire for a *goodly Babylonish garment*, Joshua vii. 21. Its beauty, its excellency, its abundant treasures, and its gates of brass, are alluded to in scriptural prophecy. History ascribes to Semiramis, queen and successor of Ninus, the honour of planing and nearly completing the building of Babylon. It is even reported. that she had two millions of men employed in the accomplishment of her magnificent enterprize. But Nebuchadnezzar, who is so often mentioned in the Scriptures, enriched it with splendid embellishments. To gratify his wife, a princess of Media, who admired the mountainous scenery of her native country, he caused the gardens already described to be constructed. Intoxicated with pride, he said, in the spirit of imperious arrogance, as he surveyed his works—Is not this great Babylon, which I have builded for the house of my kingdom, by the might and the honour of my majesty? and was thenceforth humbled to the lowest state of abasement, and the city in which he boasted was also near its fall.

Babylon taken.—In the succeeding reign it was invested by Cyrus, the conqueror of Asia. After a blockade of two years, he obtained possession of it, amid the revels of a general festival. Having turned the course of the river by means of its canals, he so completely drained it of its waters, that his army marched along the channel into the heart of the city, and easily became its masters. From this period, it sunk into comparative insignificance. Darius demolished its walls, with their gates of brass, and massacred its inhabitants in multitudes. Alexander the Great was ambitious to restore it again to the rank of an imperial city, and had commenced his repairs, when death put an end to his magnificent designs. Declining rapidly from this period, Babylon soon became a heap of ruins.

Ruins.—This great city, in the time of Strabo, had become a desert. Jerome, who flourished in the fourth century, tells us, that the royal hunts were in Babylon, and wild beasts of every kind confined within the circuit of its walls, and that the whole space was full of desolation. A traveller, in 1574, could discern great masses of ruins, but durst not approach them for fear of the wild creatures which they harboured: And Hanway tells us, in his travels, that these ruins are now so much effaced as to have left few vestiges to point out the place where they once rose in regular proportion, in all the strength and beauty of architecture. Mr Rich, as stated in his Memoir published in 1815, proceeding upon the suggestions of Major Rennel, examined the banks of the Euphrates, northward of the village of Hellah; and amid many mounds of smaller dimensions, he found one 1100 yards long, and 800 broad. Farther on he found a mass 700 yards square, named by the natives, *kasr*, or palace. A mile beyond this he came to an irregular object, varying in length from 136 to 200 feet, and rising to 140 in height. This is denominated the *Mujelibe*, from the top of which Mr Rich surveyed the surrounding plain, but could observe no other large mass in this neighbourhood. But about six miles to the southwest of Hellah he found a heap of ruins of an oblong form, 762 yards in circumference. and rising in the manner of a cone to the height of 198 feet, called *Birs Nimrod*. These ruins are now used as quarries for the construction of other cities. This circumstance exposed their interior to the inquisitive observations of Mr Rich, which he found to be composed of burnt and unburnt bricks, of several sizes and various degrees of fineness, cemented together with mortar, bitumen, and chopped reeds and straw. In some places he found pieces of wall in an entire state, eight feet thick, ornamented with niches, and strengthened with pilasters. No certain conclusion can be drawn from the information contained in the memoir of Mr Rich, but he has promised to persevere in his investigations.

Let the candid reader now compare these details with the predictions of Isaiah and Jeremiah respecting Babylon. Let him consider that they were delivered when the kingdom of Judah was on the decline, and the empire of Babylon increasing in glory, in honour, and influence, and he must be astonished at the completeness of their accomplishment. He will observe with amazement how every purpose of the Lord hath been performed against her; how she has become heaps of ruin, a dwelling place of dragons. How Jehovah of Hosts hath swept her with the besom of destruction!

Empire of Babylon.—It seems probable that the famous Tower of Babel gave rise to the name of the oldest empire in the world. The astronomical tables sent by Alexander to Aristotle, carry back its existence 2234 years before the birth of Christ. But shadows, doubts, and darkness, rest upon it, till the city of Babylon, 605 years before Christ, became, under Nebopolassar, the capital of his kingdom.

This potentate, otherwise named Nebuchadnezzar, was chief priest, and hereditary satrap, during the disgraceful reign of the effeminate Sardanapalus.

Having formed an alliance with Cyaxares, the Mede, he obtained the sovereign power through his assistance; and as Nineveh had been destroyed by fire, he transferred the government to Babylon.

Nebuchadnezzar of the Scriptures, his son, was first the associate, and then the successor of his father. He had a warlike genius, gained many victories, extended the empire by conquest, and reduced refractory provinces to obedience. From the plunder of vanquished countries he filled his capital with disgraceful riches, and, among the rest, with the sacred vessels of Solomon's temple. He was succeeded by Evil-Merodoch, a weak voluptuous prince. After some usurpations, Nabonadius, the Belshazzar of the Scriptures, and son to Nebuchadnezzar, succeeded to the throne. The reins of government were at first held by Notaris, his mother, a woman of talent and enterprize. She was careful to finish the works which her husband had commenced, and was anxious to support the tottering throne. But its total overthrow was at hand. While Belshazzar the king made a great feast to a thousand of his lords, and drank wine before the thousand, Cyrus without the walls was exerting all his powers to obtain possession of the city, an enterprise which he accomplished, to the subversion of the Babylonian empire. The king was slain, and the kingdom was divided and given to the Medes and the Persians.

Country of Babylon.—The appellations, Babylon, Chaldea, and Assyria, are frequently used indiscriminately by historians. But Babylonia seems to have been an early and a general designation of the region around the celebrated tower of Babel. While the great city described above continued to be the metropolis, Babylonia comprehended all the countries which composed the empire. But the name properly belongs to the country called in scripture Aram beyond the River, a region which lies between the Euphrates and the Tigris. These great rivers rise among the mountains of Armenia, and, flowing in the same direction, recede and approach each other in their course, till they unite their streams, and fall by one channel into the Persian gulph.

The country inclosed in these natural boundaries slopes towards its rivers by so gradual a declivity that throughout its whole length it presents the appearance of two immense hanging gardens. By the industry of the inhabitants, canals of every size were cut from the higher to the lower river, rendering it a well watered garden; so that, in respect of fertility, it even far surpassed Egypt. "In the language of Herodotus and Strabo, quoted by Gillies, it restored with increase of a hundred, and three hundred fold, all the finest kinds of grain with which it was sown or planted. The leaves of wheat and barley were four fingers broad; the whole country was adorned with palm trees, which presented the triple offerings of bread, honey, and wine; fruits in the same season were succeeded by flowers, and the soft warm soil, strongly impregnated with nitre, required only a sprinkling of water to be converted in a few weeks from an arid waste into a green paradise." This country abounded in excellent materials for building; it afforded a viscous clay, which, when formed into bricks, became fit for use by merely hardening in the sun. Its bitumen, found every where, made a firm cement, and forest trees were floated down the rivers from the woods of Armenia.

Under such favourable circumstances, it need not be wondered at that Babylonia became the first theatre of civilization, that its inhabitants were so numerous, its cities so stupendous, its arts so manifold and perfect, its riches so immense, its commerce so great, or that it should still retain a commanding influence over the imagination.

BACCHANALIA, were festivals celebrated by the ancient Greeks in honour of Bacchus. Those who took an active part in the performance of these sacred rites assumed the character of Pan, Silenus, and the Satyrs, appeared in appropriate dresses, were crowned with garlands of vine leaves and ivy, and were accompanied with musical instruments, as drums, pipes, and rattles. These festive scenes were usually exhibited in the night; and the most extravagant licentiousness and grossest debauchery prevailed. The labours of oriental antiquaries have been much occupied in tracing the origin of the mysteries of Bacchus; and later writers seem to have adduced plausible reasons for supposing that the earliest institution of these rites took place in India.

BACCHARIS, or PLOUGHMAN'S SPIKENARD, a genus of plants belonging to the Syngenesia class.

BACCHUS, the god of wine, according to ancient mythology, was the son of Jupiter and Semele. Always represented in the bloom of youth, he wears a garland of ivy or vine leaves, he holds in his hand a *thyrsus*, or staff bound with ivy, and his chariot is drawn by tigers, or lions, accompanied by his preceptor Silenus, and a band of satyrs and bacchanals. The superstitious gratitude of ancient nations acknowledged Bacchus as the author of many essential benefits conferred on mankind. Agriculture, commerce, navigation, and even the constitution of human society, have been ascribed to this divinity. His history has been a fertile subject of learned discussion. While some think that Bacchus is to be considered as the same person with Moses, others suppose that he was Nimrod or Noah; and Sir William Jones contends that he was Ramah, the son of Cush. The same accomplished oriental scholar seems to be of opinion, that the Greeks derived their Dionysus, or Bacchus, or the incidents of his history, from India. In support of this opinion, he refers to a comparison of the poem entitled *Dionysiaca* of Nonnus, and the epic poem on the same subject called *Ramayan*, the production of one of the first Hindoo poets. Bryant's *Mythology*. *Asiatic Researches*, Vol. I.

BACHELOR, a term applied to an unmarried man. Under some of the ancient governments, bachelors were regarded as a kind of degraded citizens; they were the subjects of particular enactments, and they were deprived of certain privileges. By the laws of Lycurgus they were excluded from all offices of the state, whether of a civil or military nature, and they were even prohibited from being present at the public entertainments. Among the Romans, it was not unusual for the censors to impose arbitrary fines on old bachelors; and in the time of Augustus a law was passed, by which they could not receive a legacy, or succeed to an inheritance bequeathed to them by will, except from near relations. In Britain, a direct tax was imposed on bachelors in the time of William and Mary; and, at the present day, the servants of such persons are subjected to the payment of a higher duty.

BACHELORS, under the feudal institutions, were of an inferior order to the knights; and hence they were distinguished by the title of *knights*-bachelors. Such persons as held possessions too small to bring a sufficient number of retainers into the field to enable them to display their own banner or such as were under the command of knights, came under this denomination. Their rank was inferior to that of knights, but superior to that of esquires or gentlemen. The French expression *bas chevaliers* "inferior knights," seems to point to a plausible origin of the term.

BACHELORS denote such persons as have attained the first step in the literary honours conferred by universities, as bachelor of arts, bachelor of divinity. Four years attendance are required to be entitled to the degree of bachelor of arts at Oxford; three years more are necessary to obtain that of master of arts; and seven years more to become bachelor of divinity.

BACKGAMMON, an amusing game which is played by two persons with dice and a table, on which fifteen men, assigned to each player, are arranged in a particular manner. The success of the game, it is obvious, depends partly on chance, and partly on the skill of the player in the management of his men. See Games.

BACON, Roger, an English monk, who, by his extraordinary attainments in natural philosophy, outstripped the age in which he lived by several centuries, was born at Ilchester in Somersetshire, in 1214, studied first at Oxford, and afterwards in the university of Paris; and on his return to England in 1240, when he was in his twenty-sixth year, he assumed the monastic habit among the Franciscan order. Oxford became again the place of his residence; and while his investigations were directed to every department of physical science, the astonishment at his remarkable discoveries, excited by the ignorance of the times, brought down upon him the charge of necromancy or magic, and exposed him to severe persecution. He was prohibited from instructing youth, and then subjected to close confinement. During the short pontificate of Clement IV. which lasted only three years, the severity of his enemies had either relaxed or was suppressed by higher influence. But the exaltation of his successor to the papal throne was fatal to the enlightened philosopher. He was seized in France, thrown into prison, and spent ten tedious years in a dungeon. Having once more obtained his freedom, he returned to Oxford, and died in 1292, when he had reached the 78th year of his age.

Beside the predominant studies of the times, such as grammar, logic, and theology, in which he was highly conspicuous, his knowledge of various branches of natural philosophy, and particularly of optics, astronomy, and chemistry, has not failed to excite the admiration of the present age.

Bacon has been very generally allowed to be the inventor of gunpowder; but from certain ambiguous expressions in his works, it is alleged that he was not the actual inventor, but only that he was acquainted with the nature and effects of that remarkable compound. A new edition of his *Opus Majus*, or Great Work, which comprehends an abstract of his other treatises, was published in 1733; and, beside some other productions, his *Epistle on the Secret Operations of Nature and Art, and on the Futility of Magic*, all in Latin, has been often reprinted.

BACON, FRANCIS, Lord Verulam, and Viscount St Albans, the father of modern philosophy, was born at London on the 22d of January 1560-1. His early genius, and the rapidity with which his faculties were developed, promised a rich reward for the anxiety of parental instruction, and a splendid accession to the honours of his name. The discernment of Queen Elizabeth, who had frequent opportunities of seeing him during the time that his father was Lord Keeper of the Seals, was gratified by his acuteness and good sense. A reply to a very simple and common question put to him by that princess, while he was yet a boy, is recorded as an example of readiness of mind, which, independent of the delicate flattery, did not fail to call forth her commendation. Having asked him his age, he answered, that "he was just two years younger than her happy reign." This talent of negociating words to the best advantage, according to one of his own sagacious remarks, that they are "the counters of wise men, and the money of fools," found adequate reasons for exercise in the courts of Elizabeth and her vain-glorious successor. But its pruriency, and certain indications of a kindred vice, have cast a baneful shade over the character of the philosopher.

After some years study at Cambridge, Bacon was ushered into public life and the concerns of government, by accompanying Sir Amias Powlet, the English ambassador, to the court of France. That minister, fully sensible of his qualifications, entrusted him with an important commission to the queen, which he executed in the most satisfactory manner. He was now little more than seventeen years of age. The death of his father, which occurred soon after, was injurious to his advancement, and involved him in the usual difficulties of a younger son. He betook himself, in consequence, to the study of law, in which he made such advancement, that he was deemed worthy of being named, by Elizabeth, her learned counsel extraordinary, at the age of twenty-eight. The path of greatness, so earnestly eyed by his ambition, now lay fair before him; but he had to encounter the parsimony, and perhaps, too, the ingratitude of his sovereign, though he did not scruple to solicit her good graces by paying court to her favourite, the Earl of Essex. The influence of the Secretary Cecil, who was jealous of his talents, and disliked his attachment to that unfortunate nobleman, limited his success to the promise of a reversion of a valuable office, which did not become vacant for nearly twenty years. Bacon's subsequent desertion, and indeed zealous prosecution of the favourite, when his imprudence and high-mindedness had involved him in a fatal calamity, implied a baseness of feeling still more contemptible than the inveterate selfishness of soul which

Bacon. could find patience for so long a servitude of adulation and desire. Elizabeth herself, whether from a sense of dignity, which she knew well how to sustain, or from the remembrance of an affection sufficiently vivid to shed a kind of sympathetic tenderness over her heart, was offended at the pertinacity and bitterness of Bacon's maledictions. She took care not to reward these exertions, which subjected him, besides to the just indignation of the people, who were more cordially attached to Essex than they usually are to favourites.

On the death of Queen Elizabeth, about a year after his fate, and hastened, as has generally been imagined, by sorrow for the part which she had been constrained to act towards him, Bacon appears to have been among the first of the English courtiers who "hailed the rising sun." He had the prudential policy to offer his services to James, through the medium of all the Scottish noblemen and gentlemen to whom he could possibly procure access, before that ostentatious and conceited monarch had quitted his own country, to take possession of the throne that awaited him. The celerity and amount of his successive elevations repaid his assiduity, and very distinctly proved, that this most prolific eulogist and admirer had found a suitable merchant for his ware. There was almost a strife between them for some time which should exceed; the one in fulsomeness of flattery, the other in bountifulness of giving. The comparison, which is somewhat striking, terminates in favour of the former. Bacon's dedication "Of the Advancement of Learning," is, in reality, a masterpiece of panegyric. His loyalty discovers what his religion assured him was inscrutable,—the virtues and faculties of the king. Hence he expresses his wonder "at the largeness of his capacity, the faithfulness of his memory, the swiftness of his apprehension, the penetration of his judgment, and the facility and order of his elocution." These are but samples of the exuberant mass of Bacon's commendations, the climax of which is contained in an expression virtually, if not avowedly contrived, to carry the monarch's conceit into the regions of blasphemy. "I am well assured," says the pompous sycophant, "that this which I shall say is no amplification at all, but a positive and measured truth, which is, that there hath not been since Christ's time any king or temporal monarch which hath been so learned in all literature and erudition, divine and human!" The substantial and showy recompenses on James's part, were, in rotation, knighthood, the appointment to the king's learned counsel, the office of solicitor-general, a judgeship in the knight-marshal's court, the office of attorney-general, a seat in the privy council, the appointment of keeper of the great seal, the supreme office of lord chancellor, and the titles of Baron Verulam and Viscount St Albans. These last honours were conferred on him in 1619. His prosperity now began to ebb.

The parliament of 1621, most laudably intent on the examination and redress of certain grievances, preferred the serious accusation against Bacon of having taken bribes from suitors in the court of Chancery. Investigation demonstrated his guilt, which he had the humility to confess, but which he endeavoured, in a pitiful and very fallacious manner, to palliate or excuse. He threw himself at last on the mercy of his judges, the House of Peers; but their decision savoured more of strict justice than any "compunctious visitations." He was sentenced "to undergo a fine of forty thousand pounds; to be imprisoned in the Tower during the king's pleasure; to be for ever incapable of any office, place, or emolument in the commonwealth, and never to sit again in parliament, or come within the verge of the court."

The chief causes of Bacon's fall had some semblance of virtue, or at least indicated a generosity and amiableness of disposition, which serve rather to restrain than altogether to supersede censure, and in which, particularly at this distance of time, humanity is willing, though not indeed quite able, to conceal his delinquencies. Bacon had a liberal mind, which naturally sought a splendour and immensity of style proportioned to the magnitude of his intellect and the dignity of his rank, without possessing the requisite attention to the economies of life, and without exercising the no less requisite suspicion of the common retainers on greatness. The consequences were, an expenditure beyond his income, which seduced him into dishonourable compliances, and a habit of indulgence towards his dependents and retinue, which even connived at rapacity and extortion. A single anecdote illustrates his own conviction of the mischievous effect of this last failing. One day, during his trial, as he passed through a room where some of his servants were sitting, they got up to salute him; "Sit down, my masters," said the chancellor, "your rise hath been my fall!"

Bacon was sent to the Tower, but soon regained his liberty by the mercy of the king, who forgave the fine, and ultimately, as far as he could, remitted the censure passed on him, settling him besides in a pension of L.1800 a-year. He was now about sixty years of age, and in full possession of those powers of mind by which, in spite of his errors and disgrace, he has immortalized his name in the history of learning, and claims the admiration and gratitude of every succeeding generation. The remainder of his life was spent in retirement, and in all probability amid embarrassments, sufficient, in addition to the recollection of former greatness, to have broken down and destroyed the faculties of any ordinary character, but peculiarly calculated to give energy and interest to his ardent desire for posthumous renown. It was in this period that he either wrote or revised the chief of those works which have so largely contributed to the advancement of useful knowledge. His death took place on the 9th April 1626, in the sixty-sixth year of his age, and rather more than a year after the decease of James. It appears to have been immediately occasioned by over anxiety and exercise in prosecuting some experiments; but an infirm and declining state of health, had left little hope that his life could have been much prolonged.

Lord Bacon was of the middle stature, of a graceful and pleasing appearance, but somewhat delicate; his forehead was spacious and full, early impressed

Bacon.

with marks of age; he had a lively penetrating eye, dark hair and eyebrows; his features in general expressed sedateness and gravity, but he was capable of much animation, and could assume the most agreeable insinuating aspect and address; he excelled in conversation, by readiness of remark, copiousness of illustration, and inexhaustible and familiar acquaintance with the labours of former times, and a vivacity of imagination, which displayed the force and the originality of wit, without any of its coarseness or trifling. In private life he was temperate, modest, conciliating, and ready to oblige; attached to religion without being superstitious, he seems to have venerated the creed of his country as much from a conviction of its truth as the opinion of its utility. He married, when about forty, a daughter of Alderman Barnham, by whom he obtained a considerable fortune, but had no children. Foreigners held him in high repute during his lifetime, and probably, indeed, were more just to his merits than his countrymen. The Marquis D'Effiat, who brought over Henrietta Maria, wife to Charles the First, having paid a visit to Lord Bacon, found him sick in bed, with the curtains drawn. "You resemble the angels," said the polite stranger; "we hear those beings continually talked of, we believe them superior to mankind, and we never have the consolation to see them."

The writings of this illustrious man are numerous, and embrace a variety of subjects. His chief merit, as a philosopher, consists in the complete exposure of the errors of those systems by which the schools had for so long obstructed the course of science, and the substitution of a rational logic calculated to aid man in the acquisition of a true knowledge of nature. It is his highest praise that the rapid augmentation of human power, as effected by such knowledge in modern times, is clearly referable to the adoption of his principles, and that there is no instance in which any deviation from them has conducted to beneficial discovery. Attempts have been made of late to depreciate the value of his labours, and advantage has been taken of some of his inadvertencies and mistakes, particularly in natural history, to prove either the defectiveness of his laws or his own inconsistency with them. But these attempts have succeeded much better in shewing an invidious affectation and capriciousnees of mind, than in accomplishing the object they have in view. They are, at all events, refuted at every new step in the march of science. It has rarely happened, we may add, that any of those labourers whose names are associated with important discoveries, or valuable contributions to the stock of knowledge, have closed their lives without some tribute of veneration and gratitude to the genius and philosophy of Bacon.

The most convenient, and, on the whole, the best edition of Bacon's works, in Latin and English, was published at London in 1803, in ten volumes 8vo.

BACON, John, an English sculptor, who attained great celebrity as an artist, was born in Southwark in 1740, was placed as an apprentice to a porcelain manufactory at Lambeth, and was at first employed in painting ornamental pieces of china, but, from his skill and taste in modelling, he was afterwards entrusted with that department of the business. It is no less curious than instructive to perceive the dawn of rising genius, and to mark its progress towards its brighter day. The visits of Bacon to a neighbouring pottery to which some eminent sculptors occasionally sent models to be burnt, afforded him an opportunity of seeing and examining them, and from this slight incident those imitative powers, which reached so high a degree of improvement, were called into action. His first essay seems to have been a small figure of Peace, after the antique manner, which was executed in his 18th year; and five years afterwards, in 1763, he made the first attempt to work in marble, and at the same time invented an ingenious instrument which has since been approved and adopted by other artists, for determining with more precision the measurements and proportions. The only instructions which Bacon ever received in sculpture or modelling were derived from the Royal Academy, which was not instituted till 1768, when it is probable he had made considerable improvement in his art; and in the succeeding year he was honoured with the gold medal, the first premium for sculpture bestowed by that body.

The fame of Bacon fortunately procured for him royal patronage at an early period of his career. A bust of George III. one of his first works in sculpture, and intended for the university of Oxford, was so successfully executed, and afforded so favourable a specimen of his talents, that the king ordered a second to be presented to the university of Gottingen, and the queen ordered a third. His reputation as an artist was now established; and his future works bear ample testimony that the judgment of the public was not prematurely anticipated. Among the admired productions of his chissel may be enumerated, the monument to Mrs Draper, in the cathedral of Bristol; the statue of Judge Blackstone, in All Souls college, Oxford; the monument of Lord Rodney in Jamaica; of Dr Johnson and Mr Howard, in St Pauls, London; and, above all, the exquisite monument to the memory of Lord Chatham, in Westminster Abbey, which has been always regarded as one of the finest examples of the art.

An illness of two days duration closed his mortal career in 1799; and it is pleasing to record, that his eminence as an artist was equalled by the simplicity, integrity, and respectability of his character as a man.

Bactria.

BACTRIA, an ancient kingdom of Asia, supposed to be the modern Chorasan; has the river Oxus for its boundary on the north, and Asiatic Scythia on the east; is represented as an extensive, fruitful, and populous region; successively yielded to the victorious arms of the Assyrians, Cyrus, and Alexander the Great; was afterwards overpowered by the Huns, and finally subdued by the Scythians. In the later periods of its history, this territory has shared the fate of the surrounding country, but has never been able to recover its former independence. The Bactrians, of whom laboured accounts have been drawn up, to shew that they were a wise and valorous people, seem to have been addicted to the most cruel and most abominable vices; and if it be true that they trained dogs, expressively denominated *sepulchral dogs*, for the purpose of devouring the aged and infirm, who had become a burden on the community, the learning and civilization of such a people need not be alluded to.

BADAJOS, a strongly fortified frontier town, and capital of the province of Estremadura in Spain, is about five miles from the confines of Portugal. The ancient town occupied the site of the castle; and the numerous remains of Roman, Moorish, and Gothic structures, afford ample testimony of its former splendour. The modern city stands in a fine plain on the banks of the river Guadiana, over which a magnificent bridge of 28 arches is constructed. The streets are narrow and irregular; the population is estimated at 15,000; and the manufacture of hats gives occupation to a portion of the inhabitants. Badajos is the residence of the chief civil and military authorities of the province.

BADEN, a district of Switzerland, which is bounded on the north by the Rhine, and on the west by the river Aar and the canton of Berne; comprehends about 140 square miles; includes three towns and several villages, and numbers about 24,000 inhabitants. Baden abounds in corn and excellent fruits; and the banks of the Limat, which traverses the territory, are adorned with flourishing vineyards.

BADEN, the capital of the canton of the same name in Switzerland, is finely situated on the banks of the river Limat, and is still a place of frequent resort, on account of its hot springs, which retain all the celebrity which they enjoyed in the time of the Romans, by whom they were designated *Thermæ Helveticæ*. The waters are of a saline and sulphureous quality. A pillar erected in honour of the emperor Trajan, to commemorate the benefits which the country derived from the roads which he constructed; statues in alabaster; bronze coins; and medals of the emperors, in gold, silver, and copper, are enumerated among the remains of Roman antiquity which are yet in existence at Baden.

BADEN, a margravate in the circle of Swabia in Germany, occupies the eastern bank of the Rhine, and is bounded by the Black Forest on the east and by Switzerland on the south, is a populous and fruitful territory, finely diversified with extensive forests, cultivated fields, producing rich crops of corn, hemp, and flax, orchards which afford excellent fruits, and luxuriant vineyards. The meadows, watered by the Rhine, supply a profusion of herbage to horses and black cattle; the hogs, fed on chesnuts, afford bacon of a superior quality; and the mountainous pastures feed numerous herds of deer. Iron ore, marble and agates, which latter employs the industry of a portion of the inhabitants in cutting and polishing, are enumerated among the mineral productions.

The population is estimated at 200,000. Baden, Durlach, Stolhafen, and Rastadt, are the chief towns. Various manufactures, which are said to be greatly encouraged, are prosperous. The Lutheran form of religion is established, but other forms are tolerated.

BADEN, the capital of the margravate of the same name, stands at the foot of a mountain near the Black Forest, and is chiefly celebrated for its numerous hot springs and baths. The water, as it issues from the springs, is of the boiling temperature, and it is conveyed in pipes to almost every house in the town.

BADEN is also the name of another town in the archduchy of Austria, which is greatly resorted to by the inhabitants of Vienna and the surrounding country, on account of its baths, which are in much repute.

BADGER, the English name of a species of *ursus*, which is a native of Britain. See *Ursus*, under Mammalia.

BÆCKEA, a genus of plants belonging to the Octandria class.

BÆTYLIA, were stones of a black colour, which were regarded as objects of veneration and worship by some of the nations of antiquity. The traditionary history of some of these stones asserts, that they fell from heaven. Such is said to have been the origin of one which was preserved in the temple of Heliogabalus in Syria; and such, too, was the supposed origin of another in Phrygia, for the conveyance of which to the capital the Romans appointed a solemn embassy. The speculations and conjectures of modern times concerning meteoric stones, which are known by the most decisive testimony to have fallen from the clouds, have led to the probable supposition that the ancient stones were of a similar nature, and had a similar origin.

BAFFIN'S BAY, an extensive bay between Greenland and North America, and running north-east from cape Farewell in Greenland, from the sixth to the eighth degree of north latitude. It derives its name from William Baffin, a navigator who was employed in the year 1616 in the discovery of a passage through Davis straits.

BAGDAD, a city of Turkey in Asia, and capital of Irac Arabia and of the Pachalik of Bagdad, stands on the eastern bank of the Tigris, in north latitude 33° 20′, and E. long. 44° 20′; was founded by the caliph Almansor, in the 145th year of the Hegira, which corresponds with the 762d of the Christian era, and continued for more than 500 years to be the capital of the Saracen empire. In the year 1258 it fell into the hands of the Tartars, and continued in their possession till 1393, when it was taken by Tamerlane the Great. It was long the scene of contest between the Turks and Persians; but since it fell into the hands of the former in 1638, it has remained in their possession.

Bagdad is supposed to be about three miles in circuit; the walls are of brick, and the bastions are furnished with cannon; the houses, which are generally spacious, are built of brick, but mosques and other public edifices are constructed of hewn stone. The inhabitants, composed of Persians, Armenians, Turks, Arabs, and Jews, were computed by Tavernier, in 1652, at 15,000; but in 1779 they were estimated by an English traveller at 100,000.

The commercial prosperity of Bagdad has been subjected to numerous interruptions during the long period of its eventful history; but it is still to be regarded as the great emporium of the east, and the central communication for the exchange of the silks and cotton stuffs and spiceries of the Indies, for the productions of America and the merchandize of Europe.

BAGPIPE, a popular musical instrument in Ireland and Scotland; and, from the predilection for this instrument, it has been supposed to be peculiar to those countries. But it appears to have been familiar to the Greeks and Romans; for it is represented on the ancient sculptures and coins of those nations; and indeed it seems probable that it was not unknown among other nations at an earlier date, as it is now in use in most countries of Europe. This might be expected from the simplicity of its construction.

The peculiarity of the bagpipe, from which the name is derived, consists in collecting the air into a leathern bag, from which it is forcibly pressed into the pipes by the arm of the performer. The *chanter*, into which is inserted a reed for the production of the sounds by the action of the air from the bag, is perforated with holes like the German-flute, which are stopped with the fingers. The other parts of the instrument are three tubes or drones, which are also furnished with reeds. Two of the drones are in unison with D on the chanter, which corresponds with the lowest note of the German-flute. The third drone, which is the longest, is an octave lower. The tuning of the bagpipe is accomplished by lengthening or shortening the tubes, or drones, as may be required.

The Irish pipe is the softest of the different instruments of that description known in this country; it is always played with bellows; the chanter includes a range of ten or twelve notes; and an attempt has been made to improve it with the addition of keys to one of the drones by which intermediate chords are produced. The softness of the reeds and the length of the tubes are the characteristic differences of the Irish bagpipe.

In the Highland bagpipe the drones are shorter, and, by the peculiar construction of the reeds, a louder sound is produced. This pipe affords only eight or nine good notes. It requires a strong blast to play on this powerful instrument, and hence those who perform on it either walk or stand, that they may have the full and free use of their lungs.

The Scotch lowland bagpipe is described as somewhat different in its construction, both with regard to the notes and the intensity of the sounds, which is inferior to that of the Highland pipe; and in the small Scotch pipe the chenter is not more than eight inches in length.

From the nature and construction of the bagpipe, it is obvious that it must be very limited in its powers of execution as a musical instrument; and perhaps it arises less, even from the most perfect performance, than from the effects of early associations, that it is supposed to be peculiarly adapted to those wild irregular airs which form so pleasing a part of our native musical compositions; and may it not be in some degree ascribed to the same impressive effects, that its thrilling sounds have roused and invigorated the valour of our hardy mountaineers in the onset of battle, and inspiring their dauntless breasts with heroic ardour, have led them to deeds of glory and of victory in many a hard fought field?

BAHAMA ISLANDS, called by the Spaniards *Lucayos*, include a cluster of islands belonging to Great Britain, and extending from the 22d to the 28th degree of north latitude, and from the 70th to the 80th degree of west longitude. The number of this group of islands is supposed to be not less than 500, but twelve only are inhabited. New Providence, the largest, is about 30 miles long and ten miles broad. Nassau is the chief town, and the seat of government. Guanahani, as it was called by the Indians, is remarkable as being the first landing place of Columbus, after his adventurous voyage to the New World; it still retains the name of St Salvadore, which was imposed upon it by the discoverer of America, but is commonly called Cat Island, and contains more than 700 inhabitants. The cross was erected, and formal possession taken in the name of the Spanish king, but no permanent settlement was made. In the year 1629, some English colonists arrived in New Providence, and began to cultivate the soil; and from the favourable report of Captain Sayle, who had been driven among them, a colony was sent out by the English government in 1672. But the new settlement was so much disturbed and harassed by the Spanish pirates, that it was at last abandoned, when the islands became the resort of piratical plunderers, whose depredations called forth the interference of the British government for their suppression in 1721; and New Providence was resettled and strengthened with fortifications.

The chief produce of these islands, which is cultivated for exportation, is cotton, of which 1500 bags of two cwt. each, are stated, by Mr Edwards, to be the annual quantity shipped about the year 1789; but, in 1792, it had increased to more than a million pounds. The population of the Bahama islands, in 1773, amounted to 4293, one half of which nearly included the white inhabitants. But, by the official returns in 1812, it had increased to 16,718. Of this number, New Providence contains 6084, by a census in 1810, distributed into 1720 whites, 3400 slaves, and the rest free blacks and foreigners. The other islands, from the enumeration in 1812, have 10,634 inhabitants; of which 2150 are whites, nearly 8000 are slaves, and the rest are free blacks and persons of colour. The Bahamas are divided into nine parishes, all of which, excepting one, were vacant in 1812. Two presbyterian clergymen, one of whom is resident in New Providence, and the other in Turks islands, have each an annual stipend of more than L.100 Sterling from the colony; and three methodist missionaries are established in the islands, but no public provision is allowed for their support.

BAHAR, a province of Hindostan, which lies to the westward of Bengal, and is about 250 miles long and 200 miles broad. Patna is the capital. This province furnishes a large proportion of the saltpetre which is imported into England, as well as a great deal of the cotton stuffs which are brought to this country to be printed. Wheat, rice, and pease, are extensively cultivated; and opium, from the demand of the Chinese market for that drug, is one of the most valuable productions of the province.

BAHHREIN, or BAHREN, a cluster of islands on the western side of the Persian gulph, and near the coast of Arabia, which have been long celebrated. These islands were at one time subject to the Portuguese; were afterwards alternately in possession of the Persians and Arabians, but now acknowledge the authority of the scheik of Busheer, whose chief revenue arises from the duty on the pearl fishery and on dates. Bahhrein, which gives name to the whole group, is the chief town, and is situated in Aval, the largest island. The Arabic language is spoken by the inhabitants.

BAHIA, or ST SALVADORE, a sea-port town of Brazil, and the capital of a province of the same name, stands on the outside of All Saints bay, and is strongly defended by forts and batteries. The population is estimated at 100,000, of which 30,000 are whites, an equal number includes the people of colour, and the rest are negroes. The chief trade is with Lisbon and Oporto; European manufactures and merchandize are exchanged for cotton, sugar, and coffee, various woods, gums, and balsams. Bahia is the residence of the governor-general, and the see of an archbishop; and the cathedral is a magnificent structure of European marble. N. Lat. 12° 30. E. Long. 39°.

BAIÆ, an ancient village, between Cape Misenum and Puteoli, in Campania in Italy, which the classical scholar will recognize as a favourite retreat of the Romans, to which they were attracted by the mildness of the climate, the beauty of the scenery, and the luxurious enjoyment of its warm baths, from the bustle and business of the crowded capital. Becoming a place of fashionable resort, the limited spot which it occupied was enlarged by encroachments on the sea, and by erecting, at great labour and expence, the most formidable bulwarks to protect the habitations from the fury of the waves. From a retired village it grew into a large city, which, even in its ruins, presents striking proofs of its former magnificence. The irruption of the Goths into Italy was fatal to Baiæ: from that period it declined; and what the destructive bands of the barbarians spared was finally destroyed by the resistless violence of earthquakes and inundations.

BAJAZET I. sultan of the Turks, and celebrated for his warlike achievements, was the son of Amurath I. whom he succeeded in 1389, and holds a conspicuous place in history from the severity by which he was treated by his conqueror Tamerlane, who, it is said, exposed his vanquished enemy in an iron cage. But this story is variously detailed. In a dreadful conflict, in which more than 300,000 men are said to have fallen, Bajazet was taken prisoner; and having been conducted to the tent of the Tartar prince, he was thus addressed by the conqueror: "Alas," said the emperor, "the decree of fate is now accomplished by your own fault; it is the web which you have woven, the thorns of the tree which yourself have planted. I wished to spare, and even to assist the champion of the Moslems; you braved our threats, you despised our friendship; you forced us to enter your kingdom with our invincible armies. Behold the event. I am not ignorant of the fate which you reserved for myself and my troops. But I disdain to retaliate; your life and honour are secure, and I shall express my gratitude to God by my clemency to man." But this generous declaration, connected with what followed, is alleged to be somewhat tainted with the haughtiness of conquest. Bajazet was invited to the feast of victory; the Mogul emperor placed a crown on his head and a sceptre in his hand, and gave him a solemn assurance of restoring him to the throne of his ancestors. The death of the captive in 1403, about nine months after his defeat, precluded his enjoyment of the power and honours which were conferred on his son, whom Tamerlane set at liberty, with many rich presents, and put in possession of the kingdom of Anatolia.

The story of the iron cage is deduced from a different relation of what passed between the Mogul emperor and his royal captive. The generous intentions of Tamerlane were, in some degree, frustrated by the unseasonable arrogance of Bajazet himself; the complaints of his enemies, by no means frivolous or groundless, made a strong impression on the mind of the conqueror, who betrayed a design of leading his prisoner in triumph to Samarcand; an attempt to facilitate his escape by digging a mine under his tent, seemed to justify a harsher restraint; and in his rapid movements, an iron cage on a waggon, it is supposed, might be invented, not as a wanton insult, but as a rigorous precaution. Bajazet sunk under the trial; and, in a paroxysm of despair, it is said, dashed out his brains against the bars of his prison; and thus his premature death might, without injustice, be ascribed to the severity of Tamerlane. But the conqueror warred not with the dead; a tear and a sepulchre were all that he could bestow on a captive whom the hand of death had delivered from his power. The body was conveyed, with all the magnificence and pomp of royalty to Boursa, and with great solemnity consigned to the mausoleum which he had erected in the days of his prosperity and power. Gibbon's *Roman History*.

BAIKAL, a lake of Siberia, extending from the 51st to the 55th degree of north latitude, about 300 miles in length, varying in breadth from 15 to 50 miles, and in some places exceeding 3000 fathoms in depth, and, from some superstitious veneration attached to it by the natives who inhabit its shores, is dignified with the appellation of *holy lake*. The surrounding scenery exhibits many grand and picturesque features, from the rugged aspect and great elevation of the mountains, many of which are richly clothed with waving woods. The waters of the lake are so limpid as to permit objects to be distinctly seen at the depth of 50 feet; several large rivers discharge their waters into the Baikal, but it has only one known outlet. A liquid naphtha is thrown up on the surface in some places, and is collected for burning in lamps; and the shores abound with mineral springs, some of which approach to the boiling temperature. Lake Baikal contains numerous islands; one of which, near its northern shore, is of considerable extent, and is inhabited; and large herds of cattle are reared and fattened on its excellent pastures. Storms and sudden squalls are frequent; and the short summer of this severe climate rarely passes off without nightly frosts. The snow begins to fall in August; the lake is frozen over about the end of December, and the ice melts in the beginning of May.

The sandy shores and contiguous forests of the Baikal abound with some of the rarer vegetable productions of elevated regions. Of the plants enumerated by Pallas as indigenous to its shores, may be mentioned *dracocephalum nutans*, *lycopsis vesicaria*, *triticum litorale*, called by the natives, "wild barley," which covers the shores like a cultivated crop; *polygonum sericeum*, a beautiful species of knotgrass; and in the forests and higher grounds, *lonicera cerulea, linnæa borealis, rubus arcticus, ledum palustre*, and *pyrola uniflora*. The waters of this lake abound with fishes, among which are noticed a fish resembling the herring, which is called *omul* by the natives, and is caught in such quantities that it is a source of extensive employment and great profit; several species of the genus *salmo*, carp, tench, sturgeon, and what is singular, the seal is also a native, from which it is inferred, with some degree of probability, that the lake had once a communication with the ocean. The hunting of these animals, of which it is said 2000 are annually taken, begins in April, and their skins furnish a valuable commodity to commerce and the arts.

The fisheries on this lake are of great value and importance; and a considerable trade is carried on with the northern regions of China, by navigating its waters in the summer, and by travelling over the ice in winter. But the navigation is often attended with great danger from sunken rocks in the shallower parts of the lake, and from tremendous hurricanes, which are equally sudden and severe. The inequality of the ice, the unfrozen parts of the waters, and the furious blasts from the mountains, render the passage in winter not less insecure and hazardous.

BAIKAL MOUNTAINS, a lofty ridge, which runs nearly parallel to the lake of the same name, some of which rise to such an elevation as to be covered with perpetual snow; some are clothed with extensive forests, and others present a rugged and sterile aspect. The Baikal mountains are composed partly of primitive, and partly of secondary rocks. Granite, and some of its accompanying strata, occupy the higher regions, from some of which large plates of mica, better known by the name of Muscovy glass, is dug out in considerable quantity, and is employed as a substitute for glass in some parts of the Russian empire. In the lower regions, coal, native sulphur, and some metallic ores are common.

BAIL, a law term derived from the French, and signifying to *deliver up*, because the person bailed is delivered into the hands of the person who is surety for his appearance on being called before a court. Bail is taken, either in court, by sheriffs or other magistrates, and by justices of the peace. *Common* bail is taken in cases of small importance, and seems to be rather matter of form; but *special* bail, or substantial sureties, are required in actions to the amount of L.10 and upwards. The law declares that *excessive* bail, or to a greater amount than the case demands, is not to be insisted on. In *civil* cases every defendant may be bailed; but in *criminal* matters no bail is permitted on an accusation of treason, of murder, of manslaughter, when the indictment is found; of felony, if the person charged have broken prison, or be taken in the fact; of arson, or wilful fire-raising; of being outlaws; of having abjured the realm. But bail must be admitted, when sufficient surety is offered, for persons of good fame when charged under suspicion of manslaughter, for persons charged with petit larceny, and for persons accessary to felony; and the court of King's Bench, or any of its judges in vacation time, may bail for every kind of crime. Blackstone's *Commentaries*.

BAILIFF, in the early periods of English history, was an officer appointed for the administration of justice within a certain district, and seems to have possessed authority in some degree analogous to the power of the present sheriffs; but from the suppression of some courts, and the changes in others, the name is generally limited to officers of a very inferior rank, or such as serve writs, execute summons, &c. within their liberties and hundreds. Sometimes, even in the present day, the term bailiff is applied to persons of respectability, as the bailiff of Dover castle; and the magistrates of some towns still retain the same appellation. Sheriff's bailiffs are either bailiffs of hundreds or special bailiffs. Bailiffs of hundreds are nominated by sheriffs to collect fines, summon juries, attend the courts of assize and quarter-sessions, and execute writs in their several hundreds; but in the execution of some parts of their duty *special* bailiffs, who are more skillful and more practised, are conjoined with them. Bailiffs of *liberties* are appointed by the lord within his liberty.

BAILIFF, WATER, is an officer in seaport towns in England, who searches ships, collects anchorage duties, and arrests persons for debt on the water.

BAILLY, JEAN SYLVAIN, an eminent French astronomer, was descended from a family which for several generations had been distinguished for painting, and was born at Paris in September 1736. Destined to the same profession, he had made some progress in the art, but a passion for literature and science predominated in his mind, and his early acquaintance with the celebrated geometer La Caille decided his choice, and directed his studies to the higher departments of physical knowledge. The calculation of the orbit of the comet which appeared in 1759 is recorded as the first of his labours in astronomical investigations, to which so large a portion of his time and talents was afterwards devoted. The theory of the satellites of Jupiter, and the practical use of the observations of their eclipses in the discovery of the longitude, long engaged the attention of Bailly, and brought him forward as a powerful competitor for prize questions with some of the most distinguished philosophers of his country.

The reputation of Bailly rose high on the publication of the first volume of his History of Astronomy, which appeared in 1775; and became still more conspicuous for profound research, comprehensive views, and indefatigable industry, when the fourth volume of that great undertaking was presented to the public in 1782. Beside this work, which is peculiarly distinguished by animated description, luminous narrative, and interesting detail, he was the author of numerous memoirs connected with astronomy. But his labours were not confined to these sublime investigations. His "Letters on the Origin of the Sciences, and of the People of Asia," "On the Atlantis of Plato," and "On the Ancient History of Asia," and the "Eloges," which he composed on Leibnitz, Charles V. Corneille, La Caille and others, afford incontestible proofs of great versatility of talent, powerful genius, and an accomplished scholar. He was elected secretary of the French academy in 1784; and he was the only example, from the time of Fontenelle, of the same person holding a seat in the three learned Parisian academies.

Hitherto we have contemplated this distinguished philosopher in the shades of retirement, and deeply engaged in the calm pursuits of science, employing successfully the energy of a vigorous mind in the profound researches of physical truth. Less fortunate in his political career, he encountered the dreadful storm of the French revolution, and fell a lamented victim to the savage fury of a relentless and sanguinary faction. He became an early and zealous promoter of that revolution, which, now that the consequences have been seen and felt, holds out an awful lesson to the leaders of the populace to repress rather than to encourage and excite a spirit of tumult and disorder, which, once roused, bursts forth with ungovernable fury, and involves all in general ruin. In the share which Bailly took in that memorable struggle, it is acknowledged, even by opposite parties, that he acted with integrity; but, at the same time, it is admitted, that he was influenced by misguided zeal, and dazzled with the prospect of an imaginary freedom, which the people, for whom he laboured, were not qualified either to appreciate or to enjoy.

In the assembly of the states-general, which met in 1789, he was deputy to the *tiers etat*, was afterwards chosen president, and held the same conspicuous station when the national assembly was constituted. He warmly supported all the measures of the popular party, rose high in favour with the people; and when the office of mayor of Paris was revived, he was appointed by acclamation, on the day after the memorable 14th of July 1789, when the Bastile was stormed and taken; but, in executing the duties of this high office, the salutary restraints which he was compelled to employ, in checking the unbridled fury of a lawless mob, deprived him of his popularity, and led to his resignation in November 1791.

Declining health obliged him to withdraw from those tumultuary scenes which were exhibited in the capital, and to seek retirement and quiet in other parts of France. In the peaceful retreat which he had chosen, he resumed his literary labours, and was engaged in drawing up memoirs of the astonishing events which he had witnessed, and in some of which he had acted so conspicuous a part. But the period of proscription approached; he was denounced as an enemy to the republic, arraigned before a sanguinary tribunal, and condemned to death on the 10th November 1793; and on the succeeding day he was executed near the spot where, under his authority as mayor, he had ordered the soldiers to fire on the mob in July 1791. On the day of execution his sufferings seemed to be studiously protracted. He experienced none of that sympathy and compassion which are shewn even to the lowest criminal when he is about to expiate his offences with his life, but was treated by an incensed and barbarous populace with the most ignominious indignity and cruelty. Habited in the degrading garb of the red shirt, or badge of conspiracy, and with his hands tied behind his back, he was placed in a cart, and led to the place of execution in the midst of a torrent of rain; the populace as he passed, spit and threw mud upon him, and reviled him with the most opprobrious language; and when he was ascending the platform, a spectator near him insultingly exclaimed, "Bailly, you tremble." "Yes," he replied, "but not with fear." And thus unfortunately perished this venerable philosopher, in the 57th year of his age, deplored and regretted by the lovers of science and literature, which his genius and industry had so successfully illustrated and adorned.

BAILMENT, a law term, signifying a delivery of goods in trust, upon a contract expressed or implied, as when money or goods are delivered to a common carrier to convey from one place to another, he is bound by law either to carry them to the person to whom they are addressed, or to pay the amount of the value; or if a horse or goods be delivered to an innkeeper or his servants, he is bound to keep them safely and to restore them to his guest; or if a pawn-broker receive goods as a pledge for the repayment, on a fixed day, of money lent, he is under contract to return the goods when the pledger performs his part, by redeeming them in due time. Blackstone's *Commentaries*.

BAIRAM, the appellation of two festivals which are observed with great solemnity among the Mahometans. The word, which is Turkish, signifies a *feast*. The *Little* Bairam is held at the close of the fast Ramazan, begins with the first full moon in the following months, and is observed for three days in Constantinople and throughout Turkey, and in Persia for five or six days. The *Great* Bairam is a grand festival kept by the pilgrims at Mecca.

BAKER, Sir Richard, author of various works, but best known as the writer of the Chronicle of the Kings of England, was born in 1568, studied at Oxford, discharged the duties of high sheriff of Oxfordshire, and, through imprudence or misfortune, was reduced to such poverty that his latter days were passed in the Fleet prison, where he died in 1645, and where most of his literary labours were executed; but, with the exception of the *Chronicle of the Kings of England*, which has long obtained some degree of popularity, they have sunk into merited oblivion.

BAKER, Henry, an ingenious naturalist, was born in London about the beginning of the 18th century. Little is known of his early education, but it appears that he had for some time served as an apprentice to a bookseller, and having directed his attention to study the means of curing stammering, and to the methods of teaching the deaf and dumb, these pursuits became his professional employment in the future part of his life. What was his success in this laborious and useful occupation, is not recorded, but it seems to have been beneficial to himself in increasing his fortune.

By means of the microscope, Mr Baker employed much of his spare time in examining the habits and changes of animalcula; and with the assistance of the same instrument he studied the crystallization and configuration of saline substances. He had courted the muses in early life, and had made a considerable collection of objects in natural history; but his most valuable works are *The Microscope made easy*, and

Employment for the Microscope, which may be useful to those who are engaged in microscopical pursuits. Mr Baker died in 1774. His wife was the daughter of the celebrated satirical and political writer, Daniel Defoe.

BAKING is the art of preparing bread, or of reducing meal or flour of grain, or other substances, into bread. See BREAD.

BAKOU, or BAKU, a sea-port town on that part of the Caspian sea which is included in the territory of Persia, is strongly fortified, and enjoys a considerable trade in rock-salt, sulphur, naphtha, cotton, and saffron, which are produced in the surrounding country, and are exchanged for wine and silk stuffs. The approach to the harbour is incommoded with shallows, low islands, and sand-banks, which are common on the shores of the Caspian.

The everlasting fire and the naphtha springs in the neighbourhood, have been subjects of wonder to credulous travellers, some of whom have detailed exaggerated accounts of these natural appearances. In a dry and rocky soil, about ten miles from Bakou, a sulphureous or bituminous vapour issues from the earth, and when set fire to continues to burn for a long time. The votaries of superstition have taken advantage of this phenomenon, and have erected temples, in which the Indians perform certain religious ceremonies. A hollow cane is fixed in the ground near the altar in one of these temples, and a blue flame, which, it is said, has burned since the flood, and will continue to the end of the world, issues from its upper extremity. The soil is described as a mixture of coarse marl and sand. The chemical reader will be at no loss to perceive that this inflammable gas is produced by the decomposition of certain substances under the surface, and that it is probably the same with the carbonated hydrogen gas which is obtained from coal for the purpose of lighting streets and manufactories.

The naphtha springs in the neighbourhood of Bakou, are a copious source of revenue to the khan. The naphtha, of which the principal spring is in a small uninhabited island, is of various degrees of consistence; sometimes it is in a liquid form, when it boils over and runs in a continued stream, and sometimes solid and black like pitch. If accidentally kindled, the whole course of the current, as it proceeds to a great distance in the sea, appears in a flame. The naphtha is collected in reservoirs, and it is drawn off from one to another, for the purpose of purification; it is conveyed in vessels to different parts of Persia, and is employed by the poorer inhabitants both for light and heat. Springs of hot water are found in the same vicinity, and are employed both for bathing and drinking in the cure of various diseases. The naphtha, taken internally, and used as an external application, is also regarded as a sovereign remedy in a long list of disorders, though it may be justly doubted whether it penetrates instantaneously into the blood, as has been asserted.—Hanway's *Travels*.

BALA, a small town of Merionethshire, in North Wales, occupies a fine situation at the eastern extremity of Bala-pool, a lake about four miles long and 3-4th mile broad, and seems to be of great antiquity, from the traces of Roman camps observed in its vicinity. The lake which abounds with common trout, perch, and the gwyniad, a variety of trout peculiar to certain lakes in Britain and Switzerland, is traversed by the river Dee, whose current glides on unmixed with its waters. The inhabitants, estimated at nearly 15,000, are chiefly employed in the manufactures of woollen stuffs, gloves, and stockings, and have some trade in fruit, which is an object of culture in the neighbourhood. The distance from Welshpool is 26 miles, and 195 miles from London.

BALAAM, a prophet and diviner of the city of Pethor, whose intercourse with Balak, king of the Moabites, is recorded in the 22d and following chapter of the book of Numbers. This passage of Scripture has been a fertile subject of discussion among commentators, as whether Balaam should be regarded as a true prophet or a soothsayer; whether the incidents were real, or only an illusion; and whether it ought to be interpreted in a literal or allegorical sense. The words of St Peter support the literal meaning: "The dumb ass," says the apostle, "speaking with man's voice, forbade the madness of the prophet. 2 Peter ii. 16. and in this view it is to be regarded as a miraculous interposition of heaven. Calmet's *Dictionary*.

BALACLAVA, a town of the Crimea in Tartary. See CRIMEA.

BALÆNA, the whale, a genus of cetaceous fishes See CETOLOGY.

BALAGAT, or BALAGAUT, an extensive province of the Mogul empire in India, stretches along the elevated range of mountains called the Gauts; is bounded on the west by Guzerat, and by Visiapour on the south; and abounds with cotton, sugar, and other productions of the warmer regions of the earth.

BALAGAUT MOUNTAINS, a mountainous ridge, which runs nearly the whole length of the Indian peninsula, and divides Coromandel from the Malabar country. A remarkable diversity of climate is produced by this elevated region; and on different sides of it, opposite seasons prevail at the same time. One side enjoys the warm influence of summer, while the other is exposed to the severity of winter; and the tempest rages on one side, while all is calm and serene on the other.

BALANCE, an instrument for determining the weight of bodies, by comparing them with the known weight of another body. The construction of this instrument depends on the principle of the lever; and it must be referred to that kind of lever in which the distance between the fulcrum, or point of support, and the distance between the fulcrum and weight are the same; and therefore to bring the instrument to an equilibrium, or when it is exactly balanced, the power and weight must be the same. The balance is composed of a beam, suspended exactly in the middle; and from the extremities are hung two scales for the reception of the body to be weighed, and the weights with which it is to be compared, and the equality of these is known from the horizontal position of the beam. For the more precise determination of this position, a slender rod rises at right angles from the beam; and when this rod is exactly perpendicular, the beam is horizontal, and the weights in the scales are equal. In balances of great nicety and delicacy, the axis of the beam is a fine steel edge, supported by steel planes; the beam is a cylindrical rod; a double cone, the vertex forming the points from which the scales are suspended; or a frame of a rhomboidal form; and the horizontal position of the beam is ascertained by bringing the extremities of the arms exactly in a line with the zero points of two ivory scales, fixed within the frame which incloses balances of this kind.

For the accurate construction of a balance, it may be observed, that the points of suspension, or the points from which the scales are hung, and the centre of motion, ought to be in the same line;—the arms of the balance ought to be precisely of the same length;—the centre of gravity of the beam ought to be a little below the centre of motion;—and the bulk of the beam ought not to be greater than what is consistent with strength.

A balance, materially deficient in accuracy, whether by accident or design, is easily detected. If the arms be of unequal length, as in what is properly denominated *the deceitful balance*, the inequality may not be so great as to be perceptible to the eye; and when the scales are empty, the beam may remain in the horizontal position; but the difference may be such, that nine pounds in the scale attached to the longer arm may counterbalance ten pounds in the opposite scale; and thus the purchaser of a commodity, weighed with such a balance, may receive only nine instead of ten pounds. But by shifting the weights, and the body to be weighed, the fraud is instantly discovered; for then the equilibrium no longer remains; and indeed, wherever suspicion of inaccuracy exists, this simple test ought to be resorted to. See MECHANICS.

BALANUS, a species of shell-fish, belonging to the genus LEPAS, and to the order of multivalves. See CONCHOLOGY.

BALASORE HANDKERCHIEFS, from Balasore, a town of Hindostan, a cotton fabric in imitation of the Indian manufacture, in which the borders of the handkerchief are composed of coarser threads, distributed in different ways, to produce variety in the pattern; and with the same view coloured threads are sometimes employed. In other respects this manufacture is not different from that of plain muslin, excepting that the workman must observe some precautions in rolling up the cloth, in consequence of the inequality from the coarser yarn of the border.

BALBEC, a celebrated ancient city of Syria, stands at the foot of Anti-Libanus, and is said to be included within a wall four miles in circumference. The magnificence of the ancient edifices of this city has been minutely described by different travellers, and especially the Temple of the Sun, which, from its scattered fragments and mouldering remains, seems to have been one of the most splendid monuments of architectural skill and beauty which antiquity can boast of. Balbec was visited, in 1751, by Wood and Dawkins, the former of whom published an elegant work, consisting of drawings and descriptions, under the title of *Ruins of Balbec;* by Bruce and Volney at later periods; and to those writers the reader, who wishes for minute information, may be referred. The population, estimated at 5000 in 1751, had dwindled down to 1200 in 1784, occasioned, it is supposed, by the desolations of war and earthquakes. The remaining inhabitants are poor, and meanly accommodated in miserable hovels, presenting a striking contrast with the wonderful remains of the ancient structures. A little cotton, some maize, and fruits, are the only objects of their industry. Commerce, which once flourished, and manufactures, are now little known.

BALEARES INSULÆ, BALEARIC ISLANDS, the ancient name of Majorca and Minorca, in the Mediterranean, are supposed to have derived this name from the skill of the inhabitants in the use of the sling, and were invaded and conquered by the Romans. These islands, with some others, constituted a Roman province.

BALIOL, JOHN, King of Scotland, a name well known in the history of that kingdom, as the successful competitor with Robert Bruce for the throne, to which he was preferred by the decision of Edward of England, to whose arbitration the rival claims were submitted. Acknowledging Edward as his liege lord, Baliol was crowned in 1292, and formally professed himself a vassal of England. But the interference of the English monarch in the affairs of Scotland, and the indignities to which the king himself was subjected, roused him to resistance, and compelled him to throw off his allegiance. Edward invaded the kingdom with a powerful army, required from Baliol the most abject submission, and, having formally received his resignation of the Scottish crown, conveyed the degraded monarch in chains to London. Having obtained his liberty, Baliol retired to France, lived in the character of a private gentleman, and, after some fruitless attempts to recover the throne, he died in 1314, when he had reached the fifty-fifth year of his age.

BALISTES, a genus of fishes belonging to the order Branchiostegi. See ICHTHYOLOGY.

BALK, a province of Great Bukharia in Asia, and also the capital of the same province, which is supposed to have been the chief city of ancient Bactria, and a place of some note both in ancient and modern times. In 1221, when it fell into the hands of Zenghis Khan, who cruelly massacred the inhabitants, it was adorned with 1200 temples; and the number of baths appropriated to the use of strangers and foreign merchants amounted to 200, from which some estimate may be formed of its extent and population. Most of the houses are built of brick or stone; but some of the public edifices are constructed of marble from the mountains in the vicinity. Silk stuffs are manufactured in the city; and its central position renders it a convenient place for the trade between Bukharia and India.

BALLI, or LITTLE JAVA, one of the Sunda isles, about 70 miles long and 40 miles broad, is near the eastern extremity of Java; is supposed to include more than half a million of inhabitants, and abounds in rice, various fruits, and cotton, which is manufactured into different stuffs, and thus becomes a commercial commodity, which is exchanged for the porcelain of China.

BALLISTA, from the Greek, and signifying to *shoot* or *throw*, an ancient warlike machine, for discharging darts, the force of which, if the effects be not exaggerated, was irresistible.

BALLISTIC *pendulum*, an ingenious machine invented by Mr Robins, for determining the velocity of military projectiles, and consequently the force of gunpowder.

BALLOON, in its general meaning, signifies any spherical hollow body, as a round glass vessel used by chemists, a globe on the top of a pillar, and a kind of bomb constructed of paper or pasteboard and used in fire-works.

BALLOON, AIR. See AEROSTATION.

BALLOTA, WHITE HOREHOUND, a genus of plants belonging to the class Didynamia.

BALLYCASTLE, a sea-port town of the county of Antrim in Ireland, is chiefly known for the coaleries which have been long wrought in its neighbourhood, and is 30 miles distant from the town of Antrim.

BALLYMENA, a town of the county of Antrim in Ireland, which contains between 2000 and 3000 inhabitants, has a great weekly market for brown linens, horses, and cattle, and is 21 miles distant from Belfast and 93 miles from Dublin.

BALSAM, a fragrant, resinous, liquid substance, which exudes spontaneously, or flows by incision from certain plants. See MATERIA MEDICA.

BALTIC, an extensive inland sea in the north of Europe, whose waters wash the shores of Sweden, Russia, Denmark, Prussia, and Germany. The passage into the Baltic from the northern ocean lies between the 57th and 50th degrees of north latitude, in a direction to the north-east, where it is called Skagerak; then to the south, or the Cattegat; afterwards to the south-east, through the sound of Elsineur; and, last of all, it opens into a wide expanse to the north-west, and terminates in the gulfs of Bothnia and Finland; the first stretching eastward and approaching lake Ladoga, and the extremity of the last not far distant from the arctic circle. The length of the Baltic sea, from south west to north-east, exceeds 600 miles, and the breadth is from 70 to 80 miles. The depth is seldom more than 50 fathoms.

The Baltic is studded with numerous islands, of which the islands of Aland, Bornholm, Zealand, Rugen, Oeland, Gothland, are the principal; and many rivers, some of them of considerable magnitude, as the Dwina, the Oder, and the Vistula, discharge their waters into this sea. A constant current is observed flowing into the Baltic; and to counterbalance this accumulation of waters from the ocean, a subterraneous passage has been supposed to exist, though it is probable it may be effected by an under current, as is known to be the case at the straits of Gibraltar. The navigation of the Baltic is interrupted for several months annually, by the freezing of its waters along the shores, and in bays and gulfs; and in severe winters it is frozen over in some places, and admits of travelling in carriages.

Stretching along the shores of so many countries, the Baltic sea affords unlimited facilities to commercial enterprise. The ships of all European nations, as well as those of America, enter the ports of the Baltic; and in return for colonial produce and various manufactures, carry off grain, iron, hemp, flax, tallow, potashes, timber, and other commodities. In 1792, more than 9000 ships passed the sound; in 1802, the numbers exceeded 12,000; but it seems to vary from 8000 to 10,000, and of this number one-third belongs to Britain.

BALTIMORE, a county in the state of Maryland in North America, stretches along the bay of Chesapeake, which forms its boundary on the south-east, the river Patapsco is the southern boundary, and Pensylvania lies on the north; is traversed by several rivers and arms of the sea, which render commercial intercourse easy and commodious; and abounds with iron ore. The number of inhabitants is incorrectly stated, in some accounts, at little more than 25,000, when Baltimore, the most populous town, is said to contain 30,000, and Annapolis, the capital of the county, includes 2000.

BALTIMORE, the most populous town in the county of the same name in the United States of America, is regarded as the fourth town for magnitude in North America, and one of the most flourishing sea-ports in the States; is commodiously situated on the north side of the river Patapsco, not far from its influx into the Chesapeake, possesses one of the most spacious and secure harbours in America, and enjoys all the advantages of an extensive inland navigation from rivers and creeks, which admit vessels nearly 300 miles into the interior of the country. The population in 1791 was stated at 13,000; but about ten years afterwards, if the estimate be correct, it had increased to 30,000; a remarkable proof of the growing prosperity of the place. The town stands on two sides of a creek, over which are erected two bridges to facilitate the communication; and the increase is chiefly at a place called Fell's Point, to which large ships only, on account of the depth of water, can come. The trade is very considerable. The public buildings are fine structures; and ten churches, some of which are elegant edifices, belong to different denominations of Christians.

BAMBERG, the capital of a bishoprick of the same name in Germany, was ceded to Bavaria in the distribution of the German states during the French revolution; occupies a fine situation on the banks of the Rednitz and Maine; is distinguished by its spacious streets, the elegance of many of the public edifices, and the magnificence of the cathedral; and numbers about 19,000 inhabitants, who have a considerable trade in grain, fruits, wine, saffron, and liquorice, the copious productions of the fertile soil of the surrounding territory.

BAMBOROUGH, a village and castle on the coast of Northumberland, in England. See NORTHUMBERLAND.

BAMBOUK, a kingdom of western Africa, between the Senegal and Faleme rivers, is chiefly an arid and barren region; but on the banks of the river the soil is rich and productive. Iron and gold are said to be abundant; and rice, honey, and cotton are enumerated among the productions of Bambouk. The chief town, which is described as being very populous, has the same name, and the inhabitants are negroes.

BAMFF, a town and county of Scotland. See BANFF.

BAMIYAN, a city of Great Bukharia, in Tartary, occupies a central position in one of the branches of Mount Caucasus, is a place of great antiquity, and is held in high veneration by some of the eastern nations, as is abundantly obvious from its pompous designation in the original, signifying "most beautiful and excellent city." This remarkable city appears to have been cut out of the solid rock. Twelve thousand apartments or recesses formed in this manner, are spoken of by travellers. Some of these excavations are very spacious, and are supposed to have been intended for temples; some of them have been enriched with paintings, and others are adorned with sculptured work. Two figures, also cut out of the rock, of enormous magnitude, with a third, of smaller size, stand erect in niches, and are supposed to represent some of the divinities which are the objects of worship in eastern regions. Bamiyan, indeed, is regarded by some as the metropolis of the sect of Buddha; and hence it may not be improbable, that these extraordinary artificial excavations may have been intended for the residence of the priests and devotees attached to that system of religion.

Two miles distant from Bamiyan the ruins of an ancient city are yet visible, which, in the expressive language of the country, is called *Gulghulch*, or cries of woe, in consequence of the dreadful catastrophe which befel it in 1215, when it was taken by Zenghis khan, and the inhabitants of all descriptions, and even brute animals, were put to the sword. Bamiyan is ten days journey distant from Balk and eight from Gazna. *Asiatic Researches*, Vol. VI.

BAMPTON, a market town of Devonshire, is situated on a branch of the river Exe, contains about 1400 inhabitants, who are chiefly employed in the manufacture of serges, and is distant from Exeter 22 miles, and from London 167 miles.

BANANA TREE, a species of *musa* which is cultivated in the West Indies on account of its fruit, which is employed, as well as the plantain, as a substitute for bread.

BANBURY, a town of Oxfordshire in England, stands on the banks of the Cherwell, contains nearly 3000 inhabitants, many of whom are employed in the manufacture of plush and shag-cloth, and is 22 miles north from Oxford, and 75 north-west from London.

BANCA, an island in the Indian ocean, lies between Sumatra and Borneo, is separated from Sumatra by the straits of Banca, is about 100 miles long, and 30 broad, and is chiefly remarkable for its tin mines. The king of Banca, who resides in Palambang, in Sumatra, was formerly in alliance with the Dutch, who, in consideration of enabling him, with the assistance of their troops, to preserve his authority and independence, enjoyed an exclusive trade throughout his territories. The tin mines were discovered about the beginning of the 18th century, and it is said that three millions of pounds have been delivered annually to the Dutch, by whom great part of it was sent to the Chinese market, and some of it was occasionally imported into Holland; and from this trade it has been stated that they derived an annual revenue of L.150,000 Sterling.

BANDA ISLANDS, a cluster of islands in the Indian ocean, which are sometimes called Spice, or Nutmeg islands, in consequence of that valuable spice being the chief vegetable production.—See SPICE ISLANDS.

BANDANA, a term recently applied to a very considerable branch of the cotton manufacture, carried on principally in the vicinity of Glasgow, in imitation of a species of spotted silk handkerchiefs, originally brought from India under that name. The Indian Bandanas have generally one colour for the ground, such as red, blue, or orange, and were ornamented with small spots, sometimes white and sometimes tinged with yellow, which are disposed in groups similar to the specimen exhibited in Fig. 3. Plate 26.

History.—The first attempt to imitate the Indian Bandana handkerchiefs in this country appears to have been by tying small pieces of thread round those spaces of the cloth that were to be preserved from the colouring matter during the process of dyeing. But this method being both tedious and clumsy, was superseded by another, still in practice, upon blue grounds, which is, by printing a preventative paste upon the cloth, with blocks cut out to the pattern, before it is submitted to the operation of dyeing. As these methods were only practicable when the dyeing processes were few and simple, the former has been chiefly confined to silk fabrics, though the latter has been brought to very great perfection on blue cotton goods, from the facility of dyeing this colour in a cold vat.

But as neither these, nor any other expedients that have been yet discovered, are adequate to resist the processes of dyeing a permanently fixed red upon cotton grounds, this branch of the manufacture could never have been attempted with any prospect of success on any other principle than first dyeing the cloth, and afterwards extracting those portions of the colour that were destined to form the pattern. The circumstances which led to this discovery may be briefly stated as follows:

About the year 1794, after the oxygenated muriatic acid had been successfully applied to the art of bleaching, its property of destroying vegetable colours became pretty generally known, and gave rise to a new branch of the cotton manufacture, which was then known by the name of *clouding*. The processes by which this branch were conducted, were, first by compressing the several portions of the dyed yarn which were to retain the colour, between two slips of wood, by means of screws or some other expedient, and afterwards immersing the whole in the oxy-muriatic acid. Those parts, therefore, which were exposed to the action of the liquor were discharged, leaving the colours unimpaired which were secured between the slips of wood. About the same period, from the property of the oxy-muriatic acid, thickening oils, a kind of paste, was discovered, composed chiefly of the oil of turpentine, brought to a proper consistence for working with printing blocks, which effectually secured such colours as were covered with it from the action of this acid. This paste was printed upon cloth which was either wholly or partially fabricated from coloured yarns, and exposed to the action of the oxy-muriatic acid, by which all those parts of the colours were exhausted that were not secured by the paste.

Bandana.

From an intimate acquaintance with these processes, the idea of applying the screw-press to the discharging of Turkey-red handkerchiefs, now called Bandanas, was naturally suggested; and accordingly, during the years 1800 and 1801, Mr Robert Tweedie, Turkey-red dyer to Mr Monteith at Blantyre cotton-works, made several experiments of this kind, by means of two plates of copper, with a number of holes drilled through them corresponding to the pattern, by which the discharging liquor was transmitted through the cloth. These experiments were made on single handkerchiefs, folded into one eight part of their size, and strongly pressed between the plates with screws. After applying the liquor to the perforations in the plates, he found that the spaces opposite to the holes were discharged, while those that were secured by the pressure of the plates were completely preserved.

It was a considerable time before a mode of applying these experiments to the general trade was discovered. At length, in the year 1802, the same company at Blantyre found out a method of finishing whole pieces. As soon as it appeared likely to become a trade, two of these handkerchiefs were transmitted, through the collector of excise, to the commissioners in Edinburgh, for their opinion, whether such goods were subject to the existing duties, as the spots which made the cloth two colours were not "printed, dyed, or stained," the express words of the law. The answer of the commissioners was, as they considered it, "the goods being of two colours, by whatever means it was effected, rendered them liable to the duty." In consequence of this opinion, Messrs Henry Monteith, Bogle, and Company, entered their works, and have paid a duty of 3½d. per square yard from the very commencement of the business; and such is the amazing extent to which the manufacture of this single commodity has been carried, that the duties now paid by this company alone amount to upwards of L.20,000 Sterling annually.

The acquisition to the cotton manufacture of such a valuable branch of commerce, could not fail to attract general attention; in consequence of which several other Bandana works have since been established in Scotland on principles nearly similar. But as all the real improvements which have contributed to bring these works to their present state of perfection, have originated with the company already mentioned, they have still been able to maintain a decided superiority, as well in the preservation of their fabrics as in the beauty of their colours, and the delicacy and perfection with which their patterns are executed. For specimens of the latter, see Plate 26. Figs. 3 and 4. It is but justice to observe, that the present state of perfection at which these operations have arrived, is owing, in a very considerable degree, to the discoveries of Mr George Rodger, the manager of the works, who has held that situation for many years; and who, without the knowledge of the company, had turned his attention to the discharging of Turkey-red cloth, and brought it to no small degree of improvement as early as the year 1802.

Apparatus employed.—The principal part of the apparatus employed in discharging Bandana handkerchiefs, is the common screw-press, representations of which will be found in Figs. 1. and 2. Plate 26. The frame, and other parts that have much stress to bear, are now made of cast-iron. A, Fig 1. is a bed of cast-metal, on which rests the square-frame of cast-iron B, and to which is fastened the under plate *a*. C is another frame of cast-iron, to which the upper plate *c* is attached. A horizontal view of this plate, with the perforations through which the discharging liquor is transmitted, is given in Fig. 2. At *d* is a small rim round the plate, to prevent the liquor from running over its edges. The plates are sometimes made of copper, but more frequently of lead, hollowed out to suit any particular pattern.

Process for handkerchiefs.—When the piece of cloth which is to be discharged is sufficiently stretched, and folded into handkerchiefs, generally a dozen in each piece, it is placed in the press, between the two plates, and the upper plate is screwed down with the force of four or five men acting on a lever fourteen feet long. The liquor is then applied, and all the colour exposed to its action in passing through the plates, is extracted. After the discharge is completed, the cloth is immediately immersed in water, to prevent the fabric from being injured by the corroding quality of the liquor.

For running patterns.—Although the mode of folding the piece into squares, and finishing one of these pieces at each change of the press, be not very objectionable when applied to handkerchiefs, when an entire set of the pattern is completed at one operation, yet when the pattern is to be continued from one end of the piece to the other, as in garments, &c. this method will be found inadequate, as the figures which constitute the pattern would stand reversed in each fold. To obviate this, it is only necessary to lay twelve or fourteen pieces together after being properly stretched, and, commencing at one end, the process may be continued, progressively, till the whole be completed.

Power applied to the press.—It has been suggested, from the great force necessary to set one of these presses, by the present mode that the hydrostatic press is peculiarly adapted to this operation. This suggestion, however, has not yet been acted on in any of the Bandana works in the vicinity of Glasgow, nor we believe in any other place. From a very little consideration it will appear, that a uniform pressure must be maintained on the cloth during the whole operation of discharging the colours; otherwise, on the smallest relaxation of the press, the acid would insinuate itself between the edges of the plates at the perforations, and injure those parts of the colour which are intended to be preserved. From the imperfection of the valves, therefore, and the great pressure on the leather and other materials of which this apparatus is composed, the hydrostatic press has not yet been made sufficiently free from leakage to preserve the requisite uniformity of pressure for any length of time; and hence, till this objection can be obviated, it does not appear that the Bandana work can derive any advantage from this otherwise very useful and ingenious invention. The complicated apparatus necessary to give the screw a perpendicular or rather a circular motion, and the difficulty of ascertaining the precise moment when the apparatus must be discongaged from the power, to prevent the machinery from being broken in pieces, have likewise been urged against the application of the steam-engine to the Bandana press; so that until all these objections can be satisfactorily removed, the present mode of working these presses by manual labour appears to be the most eligible.

Chemical processes.—Before the discovery of the oxy-muriate of lime, or common bleachers salt, by Mr Tennant of Glasgow, the discharging liquor was prepared from the black oxide of manganese and the muriatic acid. The oxy-muriate of lime has now been adopted in all our Bandana manufactories. But it must be observed that the solution of this salt, in its combined state, acts only as a bleaching liquor, and requires to be disengaged from the lime, by means of another acid, before it can be effectually applied to the discharging of colours. Upon this consideration another method of extracting the Turkey-red colour from cloth has been recently invented, and a patent obtained for it by Messrs Thomson and Chippendale, printers in Lancashire. The principle on which their process proceeds is, to print a very strong acid, in the consistence of a paste, upon the dyed cloth, and afterwards exposing the whole piece to the action of a solution of oxy-muriate of lime, or the common bleaching liquor; and whenever the acid and solution unite, the colour is extracted.

Blue ground.—We have hitherto directed our attention to that species of Bandanas which is manufactured from the Turkey or Adrianople red; but as the blue grounds, though now forming a branch of calico printing, has an equal claim to Indian extraction, it may not be improper, under this head, to take some notice of the processes by which their manufacture is conducted. After the cloth has been sufficiently freed from impurities, and whitened, it is put through the calender, to give it a smooth and evenly surface. The preventative paste, formerly noticed, is now printed on with blocks, and when dry the piece is stretched and folded upon a kind of tenters, fixed in a square frame, leaving about an inch and half between each fold, in order to expose its surface equally to the colouring matter. The frame is suspended by a pulley, over a square blue vat, by means of which it may be raised and lowered during the process of dyeing. When the cloth has acquired the requisite shade, the paste is washed off, and the colour raised with a little oil of vitriol, (sulphuric acid,) diluted with water.

Preventative paste.—In a manufacture of this nature much diversity of opinion will, no doubt, exist, with respect to the best composition for these preventative pastes. The following recipe may afford some assistance to those who are inclined to make experiments of this kind.

Dissolve, in three quarts of water, one pound of the sulphate of copper, (blue vitriol,) to which add $1\frac{1}{2}$ oz. tallow, which has been previously melted and dropt into water; boil the mixture, thicken it with pipe-clay, and boil again for about ten minutes; then add a quart of gum liquor, made in the proportion of 2 lbs. gum Senegal to the gallon of water; let the whole boil again about ten minutes longer, and then take it off. When the liquor is cold, add four ounces measured, or one quarter of a pint of aquafortis, killed with copper. Some add to this a little verdigrease.

BANDITTI, derived from the Italian, and signifying *proscribed*, or *outlawed* persons, is an appellation originally applied to bands of robbers who infest the highways of Italy and Sicily, but has been extended to persons of similar character and pursuits in other countries, who act in opposition to the laws and regulations of civil society. In Sicily they have become so numerous and powerful, and have possessed themselves of such secure places for shelter and retreat round the eastern regions of Ætna, that no attempts yet made by the police of the country have succeeded in their suppression or extirpation. On the contrary, it has been deemed prudent policy in the government to connive at their depredations, and in some measure to consider them under its protection. When any of this society are disposed to retire from the mountains and forests, the Prince of Villa Franca admits them into his service, treats them with kindness and confidence, and finds them scrupulous and unshaken in their fidelity. As they are feared and respected in the country, travellers usually hire some of them as attendants in going from place to place, and in this way they are fully protected from insult and imposition in their intercourse with the natives.

BANDON BRIDGE, a town of the county of Cork, in Ireland, was begun about the beginning of the 17th century, by the first Earl of Cork, in a marshy spot on the banks of the Bandon, and has risen to such importance as to contain 12,000 inhabitants, who are engaged in woollen, linen, and cotton manufactures. The river Bandon is partly navigable, and discharges its waters in the harbour of Kinsale.

BANFF, a county in the north of Scotland, which has the Moray frith for its boundary on the north, Morayshire on the west, and Aberdeenshire on the east and south; is about 55 miles in length and 25 in breadth, and includes an area of more than 700 square miles.

General aspect.—Banffshire presents great inequality of surface. The inland parts of the county rise to a considerable elevation above the level of the sea. Cairngorum, the wide base of which is partly in Banff and partly in Morayshire, is 4050 feet high, and is famous for the smoky rock crystals which are designated by its name; two other mountains exceed 2000 feet in height; and Cullen-hill, at no great distance from the sea, is 1100 feet above its surface. While the summit of Cairngorum is covered with almost perpetual snow, the lower regions are clothed with extensive tracts of pine trees; and some of the less elevated mountains are richly adorned with waving woods to the very tops. Many of the vallies spread out into beautiful flats; the banks of the rivers are strikingly romantic; the sea-coast is chiefly bold and precipitous; and, on the whole, few places in Scotland can boast of a larger share of picturesque scenery.

Rivers.—The Spey, one of the noblest rivers of Scotland, forms part of the western boundary of the county, and some of its tributary streams have their sources in the elevated districts. The Deveron on

the eastern border of the county, is enlarged in its course by the Boyne, the Isla, and other smaller rivers, traverses a fertile and varied district, and discharges its accumulated waters into the Moray frith at the town of Banff.

Natural history.—The climate of this county is rather moist, although it is not found to be unhealthy. A light sandy soil prevails in much of the flat grounds near the sea; but a deep clay is more predominant in the more elevated districts.

The mountains of Banffshire are chiefly composed of granite and other primitive rocks. The beautiful variety of that rock, called graphic granite, which, by the distribution of the quartz, one of its constituent parts, exhibits the appearance of Hebrew characters, has been long met with in detached blocks, from which the cabinets of collectors have been supplied with specimens; but the native repository has been lately discovered. The cavities of the same rock are no doubt the original sources of the cairngorum crystals, which are usually dug out of the alluvial soil at the bottom and on the sides of the mountains, and afford lucrative employment to many of the inhabitants. Limestone is abundant in many places, and marble is not a rare rock. What is called Portsoy marble, which is the serpentine of naturalists, a beautiful mineral substance, much employed for ornamental purposes, is disposed in strata nearly in a vertical position, and alternating with marble or limestone at the harbour of Portsoy, from which it derives its name. Sandstone, both red and white, appears in different places along the shores. Some indications of metallic ores, as those of iron and lead, have been observed, but they have not been prosecuted or wrought. The chief supply of fuel is derived from extensive tracts of peat in the interior districts of the county.

Population, towns, &c.—The population of Banffshire was estimated in 1801 at 35,807, and in 1811 at 36,668. The real rent of the county was stated in 1798 at L.43,490 Sterling. Beside the usual labours of agriculture, the inhabitants are engaged in the manufactures of linen and woollen, in bleaching, tanning, and distilling. The white fisheries along the shores, and the salmon fisheries at the influx of the larger rivers into the sea, afford active and profitable occupation. The salmon-fishing on the Spey sometimes yields an annual revenue of L.6000, and that of the Deveron at Banff L.2000.

Banff, the capital of the county, and Cullen, which are royal boroughs, Portsoy, Macduff, Gardenston, and Troup, are the principal towns and villages. Cullen, Portsoy, and Macduff, contain each about 1000 inhabitants. Linen and damask manufactures, with fishing, are the chief occupation of the inhabitants of Cullen. The manufacture of thread and linens is carried on at Portsoy; and the fisheries on the coast, and the digging out and polishing of serpentine, give employment to another portion of the population. Macduff, which is at the distance of a mile from Banff, is also a fishing village, with a pretty good harbour, and some trade to Leith and London.

Husbandry, &c.—The agriculture of Banffshire, from the nature of the soil and surface, is not conducted on a large scale. Modern improvements have not been neglected, and their beneficial effects appear in the abundance and luxuriance of the cultivated crops. But a large proportion of the county is better fitted for the grazing system. Besides domestic consumption, the hilly pastures of Banffshire afford a considerable supply of sheep and cattle to the markets of the south.

The hand of art has not been slow in improving the beauties of nature in those places which have been selected for the residences of some of the great proprietors in this county. Duff-house, the elegant mansion of the Earl of Fife, stands in a fine lawn surrounded with extensive plantations, in the vicinity of Banff; Cullen-house, a seat of the Earl of Findlater, occupies a romantic and well wooded spot, on the banks of the river, near the town of Cullen; and the princely residence of the Duke of Gordon, on the banks of the Spey, although not included in the county, is a magnificent ornament to its western boundary.

Antiquities.—Numerous remains of castles and baronial residences are still visible in Banffshire; and various places are still commemorated where the Scots defeated and triumphed over the Danes, long a troublesome and active foe on the northern shores of the kingdom; but if it be true that the skulls built in the walls of the old churches of Gamrie and Mortlach, belonged to their invaders, it must be admitted that our ancestors have chosen a barbarous and unseemly monument as a memorial of their victorious struggle.

In the interior districts of Banffshire, the Gaelic as well as the English language is spoken by the inhabitants.

BANFF, the capital of the county of the same name in Scotland, stands on a declivity on t e western bank of the Deveron, and near its influx into the Moray frith, is a royal borough, and joins with Cullen, Elgin, Inverury, and Kintore, in the election of a member of Parliament. Banff was erected into a royal borough in 1372; but traditionary history carries back the date of its erection to a remoter period of antiquity.

The situation of Banff is airy and agreeable. Some of the public buildings lately erected, and the bridge over the Deveron, are elegant structures. The population exceeds 3000. The principal manufactures are linen, stockings, thread, soap, and candles; and a portion of the inhabitants are engaged in brewing, rope and sail-making, and in the extensive salmon-fishery at the mouth of the Deveron. The harbour has been improved. Grain, cheese, and butter, salmon, cod, and ling, are exported, and the imports consist of all kinds of goods for the supply of the town and neighbourhood.

An academy, established in 1786, is still ably conducted by proper masters, who instruct the youth in the knowledge of languages and in the various practical branches of education. Banff is 165 miles from Edinburgh.

BANGOR, a small city of Caernarvonshire in North Wales, stands at the head of a bay of the same name, and near the northern extremity of the straits of Menai, and is a place of great antiquity, as appears from the see having been erected in the sixth century. A single street, not very regular, includes the whole population of nearly 2000; and from Penrhyn harbour, in its vicinity, great quantities of roof-slate are exported to London and other places of the kingdom. Bangor is 250 miles north-west from London.

BANGOR, a sea-port town of the county of Down in Ireland, stands on the south side of Belfast or Carrickfergus lough. The situation is dry and agreeable; the streets are spacious and clean; many of the houses are neatly built, and the harbour admits only vessels of small size.

BANIAN TREE, the *ficus religiosa*, Lin. is a singular vegetable production, which is the object of great veneration among the natives of eastern regions, and hence the origin of the specific name. From the horizontal branches of this remarkable tree suckers are sent off, which stretch toward the earth, strike into the soil, and take root, and at last, from one plant, an extensive grove is produced. In some parts of India the banian tree may be regarded as a kind of natural temple.

BANIANS, a religious sect in India, whose belief in the doctrine of transmigration of souls is so strong, that they will not destroy any living creature, even the most noxious animals, on any account whatever, and are so extremely scrupulous in their intercourse with persons of any other religious faith, that they regard themselves as polluted by touching them, or the vessels they use. The appellation, *Banians*, is applied generally to all the idolatrous tribes of India who are not of the Mahometan persuasion; but, in a more restricted sense, it denotes one of the four principal Indian casts. The Banians form the class of merchants, and, consequently, all commercial affairs are managed by them. They are the brokers and bankers of India, and are described as a frugal, honest, and humane people.

BANK, an institution for facilitating commercial transactions, by affording security for money, issuing a convenient substitute for coin or bullion, and effecting payments of accounts, or settlements of balance, between parties at a distance. It is a modern invention, which has had the most important operations on the interests of the different kingdoms and states where it has been established, and, consequently, merits very particular consideration. The general principles form a striking feature in commerce, as now carried on throughout Europe. It is proposed to give a summary account of some of the most remarkable examples of the institution.

Bank of Venice.—The first regular bank appears to have been established at Venice in the middle of the 12th century, and has served as a model to which, on the whole, succeeding times have pretty uniformly adhered. It originated in the embarrassment of the republic's finances, occasioned by long and expensive wars, which required the aid of a LOAN from the subject. The contributors to this expedient became creditors of the state, which was security for the debt, and engaged to pay an interest of 4 per cent. per annum. An office was appointed for the regular discharge of this interest, and the management of the general fund. This, under various judicious laws, and sundry modifications of the original plan, constituted the Bank of Venice, which by its good faith, punctuality, and extensive concerns, attracted universal admiration, and conferred the most essential benefits on Europe. Its prosperity was greatly owing to an edict of the government, which enjoined the larger payments of merchants to be made in its own notes, and required debtors to lodge their money in the bank, for which a transference was made to the amount in the name of the creditor, who was paid not in money but in *banco*, or bank notes, except in certain peculiar cases, where coin was needed for retail, or to be taken abroad. In this way the wealth of the state flowed into the bank, to be used as opportunities of profiting itself and benefiting the community presented.

Bank of Barcelona.—At the distance of nearly three centuries, the magistrates of Barcelona established a kind of bank, under the title of "Table of Exchange," which properly enough indicated its nature and object. It negociated bills of exchange as well for foreigners as for natives, and therefore vastly promoted the interests of commerce. The city itself was responsible for the validity of this institution.

Bank of Genoa.—The bank of Genoa commenced in the beginning of the 15th century, also under the sanction and with the security of the government. Its management was generally entrusted to a board of the citizens, but frequently underwent modifications, to suit a change of circumstances occurring within half a century from its origin. Bills of exchange, and other pecuniary instruments, were become prevalent throughout the Italian states, chiefly owing to the revived commerce with the East, and were generally transacted in some of the institutions now mentioned.

Bank of Amsterdam,—a remarkable establishment, bearing a somewhat different character, opened at Amsterdam in 1609. The extensive, and extending trade of Holland, in which this city so largely participated, brought immense quantities of foreign, debased, and injured coin into the market, so as to perplex and impede mercantile transactions, and give occasion to various fraudulent and injurious practices. In order to prevent or remedy these and other inconveniences, the magistrates, with the authority of the States, erected a bank-office for the reception of every kind of coin at its real intrinsic value, in the standard money of the country, for which, after a small deduction for defraying the expence of recoinage and other necessary demands, they gave credit in their books. They thus declared themselves the perpetual cashiers of the inhabitants; and as, for the more effectually answering the purposes intended, they required all payments above a certain sum, and bills of exchange, to be made in the bank, merchants were necessitated to open accounts with it, and to use its notes in their cash transactions. These notes, or bank receipts, in fact represented property no less effectually than money, and had the important advantage of being far less variable in value, besides being more readily conveyed, and as capable of transfer. Bank money, therefore, bore a premium from the commencement, and consequently few persons cared to ask payment in specie at the bank, where it was generally believed to be preserved to the full amount of current paper. An additional reason for declining such a step, was the circumstance of a certain proportion of the sum being demanded as a charge for keeping the money that had been deposited. The amount of the capital of this bank was never correctly known. It originally consisted of the whole coin deposited in it, and which the bank was bound to restore on demand. But in process of time, and from various causes of prosperity, the capital became vastly larger. The city was security that there should always remain as much bullion in the bank as corresponded to the receipts issued by it; and there is every reason to believe that, amid all the revolutions which occurred in the government of Amsterdam, this condition was faithfully maintained. Its management was committed to the four reigning burgomasters, who were chosen every year. It was their duty, on coming into office, to visit the treasure, and compare it with the books; they received it with oaths, and in the same manner delivered it over to their successors. An evidence of the caution and conscientiousness with which its concerns were conducted, is exhibited in the fact, of there being no example of accusation against any of the parties to whom it had been successively entrusted, in the course of their political ascendancy. The city of Amsterdam derived a very considerable revenue from its bank, but was still more indebted to it for the promotion of its mercantile interests and its consequence among the commercial states of Europe.

Bank of England.—In the year 1695, a charter of incorporation was granted by William and Mary of England, to certain individuals, under the name of "The Governors and Company of the Bank of England," in consideration of a loan of L.1,200,000 to government, at the rate of 8 per cent. interest, and the additional allowance of L.4000 in lieu of house expenses.

Original constitution.—The merit of projecting this stupendous establishment is due to William Paterson, a native of Scotland, assisted by Michael Godfrey, a respectable gentleman of London. They appear to have taken the Bank of Genoa for their model. The charter, which was granted for twelve years, debarred the company from borrowing under their common seal, without act of Parliament, and also their trading, or suffering any persons to trade for them, in any goods or merchandize, but permitted their dealing in bills of exchange, and trafficking in bullion and foreign coin. By the constitution of the company, a governor, deputy-governor, and twenty-four directors were to be elected from the proprietors annually, for the management of the common concerns, but not more than two-thirds of the directors of the former year could be chosen. A requisite qualification of a governor was the possession of L.4000 stock; and of a director, the half of that quantity; and the electors were to hold L.500 stock in order to be entitled to vote at general courts.

Increases its capital.—By an act of Parliament in the 8th and 9th year of William, the company enlarged their capital stock to L.2,201,171, 11s. Bank stock was now declared a personal and not a real estate; and it was now enacted, that to counterfeit or forge the common seal of the bank, or any bank-bill or note, or to alter or erase such, shall be felony without benefit of clergy. The advantages which this establishment conferred on the community, and the support it was capable of rendering to the government, seemed to entitle it to every encouragement and protection which the laws could effect. The capital was doubled in the 7th of Queen Anne, when the company advanced L.400,000 more to the government; and in 1714 a farther advance was made of L.1,500,000. In the 3d year of George I. the bank agreed to cancel L.2,000,000 of exchequer bills, which made the total advance to government amount to L.5,375,027, 17s. 10½d.; the interest on the capital stock was now reduced to five per cent; and it was permitted to the bank to call from its proprietors such sums of money as a general court should think necessary, in proportion to their interests, under certain penalties on non-compliance. The interest on the last L.2,000,000 lent to government was afterwards reduced to four per cent.

By the year 1746, the bank had advanced to the government, on various occasions, L. 11,686,800, which formed its undivided capital, while its divided capital, which had been accumulating by several calls and subscriptions, amounted to L.10,780,000.

Renews its charter.—Loans.—In consideration of the renewal of its charter the bank agreed, in 1764, to pay government L.110,000, and to advance L.1,000,000 on exchequer bills, to be returned in 1766. The charter was accordingly extended to August 1786, and the interest on the stock was raised. A farther extension of the charter to August 1812, was afterwards obtained by an advance of L.2,000,000 on exchequer bills, at three per cent. In order to effect this advance, a call was made on the proprietors of eight per cent. on the capital stock, which was, therefore, increased to L.11,642,400, the dividend being at the same time raised to six per cent. The total advances to government, on the security of certain taxes and duties, and exchequer and treasury bills, amounted, in 1782, to L.9,991,678, which was reduced in 1786 to L.6,634,872. Comparatively small, though frequent, fluctuations took place between this period and 1800, when, in consideration of a farther renewal of the charter to 1835, the bank agreed to advance the sum of L.3,000,000 for the public service, free of interest, during six years. On the expiry of this term in 1806, it was at last determined that this loan should be prolonged during the war, at an interest of 3 per cent. This was certainly an accommodation to the public; but in the following year the chancellor of the Exchequer thought himself entitled to some farther compensation for the profits made by the bank on the sums of public money then deposited in it, and which amounted to nearly L12,000,000. Another loan was accordingly granted of L.3,000,000, free of interest, until six months after the conclusion of a definitive treaty of peace. Both these loans becoming due in 1814, that of 1806 was liquidated, but the other was renewed till April 1816. A new arrangement was then made, by which this was prolonged at 3 per cent. interest, in return for permission to add L.2,910,600 to the bank capital. Government was farther accommodated at the same time by an advance of L.6,000,000, at the rate of 4 per cent. In this manner the debt of the public to the Bank of England has accumulated to the enormous sum of L.20,686,800.

Circulation.—The circulation of Bank of England notes has progressively increased in successive periods from the year 1718, but not in consecutive years. This is proved by accounts laid before Parliament, from which some particulars may be extracted, illustrative of the growing prosperity of this institution.

In 1718 the amount of notes issued, which were all for L.5 and upwards, was L.1,829,930. In 1754, including bank post-bills, the circulation amounted to L.3,975,870. In 1778 it was very nearly double this sum, being L.7,540,070; but it fell somewhat short of this in 1783 and 1784. In 1791 it reached L.10,689,510, and increased in the two following years. Then there took place a gradual diminution for four years, so that the amount in 1797 was only L.9,204,500. During the next year, in which notes under L.5 were issued, in addition to those for larger sums, as formerly used, the amount was L.10,778,120. A rapid augmentation followed till the year 1802, when the circulation was L.16,244,115. The next year displays a falling off, the amount being only L.14,971,170. The fluctuating, but remarkable increase for the last eleven years will be seen from the following table:

Year.	Amount.
1806	L.16,432,380
1807	16,035,950
1808	16,919,275
1809	18,105,855
1810	19,452,930
1811	21,781,380
1812	23,881,710
1813	23,686,105
1814	25,517,550
1815	26,803,526
1816	26,594,360

Profits.—The profits of the Bank of England arise from various sources, of which the chief are: the interest paid by government for the loan of money; the allowance made for managing the public debt, which, in 1726, was L.360 *per* million, increased afterwards to L.562, 10s. but reduced, in 1786, to L.450, at which it continued till 1807, when it was farther reduced to L.340 *per* million, on the first *six hundred millions* of debt, and to L.300 *per* million on the excess above that sum; the allowance for receiving contributions to loans, and paying dividends on the public funds, the former being L.800 *per* million; an allowance on every lottery contract of L.1000; an allowance for advances on exchequer bills, or accommodating government with temporary sums on security, or in anticipation of the proceeds of taxes; the interest of stock held by the company in any of the public funds; the purchase and sale of such property as the law allows; and the discounts on bills of exchange, and the vast circulation of its notes, especially since the suspension of cash payments in 1797, to be immediately explained. The increased operation of some of those causes, during the last wars, is imagined, on good grounds, to have yielded about 25 millions of profit in less than twenty years. The dividend on the shares has consequently improved, and there has been a corresponding rise in the value of its stock. Thus, in 1797, bank stock was averaged at about L.125 *per cent.* whereas at present (1817) its market price is more than double that sum.

Suspension of cash payments.—The alarm of the country in 1793, had an injurious effect on public credit. Specie became scarce, paper-money was depreciated; the bank, unusually called on to answer its current notes, thought it necessary to refuse assistance to the mercantile community, and, on the same principle, scrupled to increase its issue of paper. The consequences were, a general deficiency of money, and the prevalence of bankruptcies. Parliament came forward to the relief of the commercial public, by the offer of a loan to a large amount, in the form of exchequer bills, which had the most salutary effects. Confidence was restored, money circulated freely, and a state of comparative prosperity ensued till 1795. The bank then became less liberal in discounting bills, in consideration of the large advances made to government. A similar effect to what had been before experienced was the result; and this was vastly aggravated in the following year, by the apprehension of invasion, which induced a rapid and large demand for specie at the bank, in place of its notes, now considerably discredited, and justly thought useless, in the event of such an apprehension being realised. The bank, in order to remedy or prevent the excessive drain of its coffers, diminished its circulation. This augmented the distress, and ultimately even quickened the demand for specie. In these circumstances, and fearing the exhaustion of their coin, the directors held communication with the minister, the result of which was an order in council, dated on Sunday, the 26th February 1797, to suspend the payment in specie, which was soon afterwards confirmed by an act of Parliament, and has since been renewed till 1818. The utmost surprise and alarm followed this memorable event, which, however, after very serious discussion, received a parliamentary justification. Some other steps were afterwards required to give full effect to this suspension; of these, the most important was an act rendering Bank of England notes a legal tender in payment of debts. The public got gradually accustomed to this new system, and for several years transacted business with very little aid from the precious metals.

Banks in Scotland.—The Bank of Scotland was established within a year after the Bank of England, and on the suggestion of the same individual. Its original capital was L.100,000 Sterling. The affairs are managed by a governor, deputy, twelve ordinary, and twelve extraordinary directors, elected annually. It has many branches in the country towns, and is understood to have proved a prosperous concern. The Royal Bank of Scotland, which was not established till 1727, is conducted on similar principles.

There are few large towns in England or Scotland in which banks are not established, on the security of individuals or companies. These generally discount promissory notes, and in many instances issue notes of their own, besides undertaking the more common, but highly beneficial business, of negociating accounts, by the purchase and sale of bills, and the reception and transmission of money.

Cash Accounts.—A peculiarity in several of the Scotch banks has greatly contributed to succour the industry and spirit of enterprise in the people. This is the system of cash accounts, which are powers granted to individuals, or companies, on security of sufficient persons, to draw out money to a certain amount, at the rate of five per cent. to be afterwards returned or accounted for, at an agreed on time of balancing. Such accommodation is equivalent to the occasional loan of money, and enables those who have no capital of their own to engage in extensive and profitable concerns. The banks themselves are benefited by it, by the circulation of their notes, in addition to the interest for money advanced; farther, it is believed they have rarely been injured even by the failure of the party, as according to the bearing of the bond, which specifies the nature of the transaction, all the persons who sign it are conjointly and separately responsible to the full amount of the sum drawn. These persons are generally known by the name of cautioners, and are usually two or three in number, the friends of the party obliged, and of approved respectability and substance.

Bank of Ireland.—The Bank of Ireland was established in 1783, with a capital of L.600,000, which was given to government in loan at 4 *per cent.* There was nothing peculiar in its management. Its charter was renewed in 1809, on conditions of its adding to its capital one million of stock, to be raised by a contribution from the proprietors at the rate of L.125 *per cent.* and disposed of to government in loan at 5 *per cent.* and its engaging to manage the public debts and loans free of charge to government. Something like this last service has been suggested, it may be mentioned, as due by the Bank of England, in return for the profits on the public funds committed to it, and the balances remaining with it, which are said to have been sometimes to a great amount. The bank of the United States is understood to act on this principle, and to charge nothing to government for managing the public debts; and it was lately mentioned, (February 1817), in the House of Commons, by Mr Grenfell, to whom the country is much indebted for his labours to bring the whole subject of the Bank of England before the public, that the Globe Insurance Company had, in reality, offered to ease the government of this expence. In times of distress, like the present, Parliament may be expected to devise some means for accomplishing so desirable a saving. But, to return.

The suspension of cash payment in 1797 extended to Ireland, after which its bank circulation so largely increased as to produce a rise in the price of bullion, and a depression in the value of paper money. Serious inconveniences were the result, till within these few years, in consequence of interference on the part of the legislature to check an exorbitant issue of private notes for small sums, and other evils, bank paper has been restored to its credit. The price of Irish bank-stock has been on the rise for the last twenty years.

Some particulars, in the history of the two French banks, deserve to be recorded.

First bank of France.—The first, which was projected by the famous John Law of Lauriston, in Scotland, was opened at Paris in 1716. Its objects, according to that singular man, were most beneficial; "to increase the quantity of circulating coin, check the progress of usury, promote the exchange between the metropolis and the provinces, allow foreigners an opportunity of acquiring funds in the kingdom, and enable the people to pay the heavy taxes imposed on them;" its general plan and arrangements were certainly judicious and commendable. The original stock might amount to L.300,000 Sterling, of which Law and his brother William were the principal proprietors. The only recompense he required for the benefits thus promised, was the privilege of managing the bank for twenty years, and permission to reckon by bank-crowns in all his transactions, as always of one weight and denomination, and consequently not liable to fluctuation in value. This last condition was asserted to be essential, in order to acquire the confidence both of natives and foreigners. The project had a flattering aspect, and obtained the sanction of government. Its immediate effects were most agreeable. Exchange with Holland and England rose in favour of Paris; at the general meeting of the proprietors in December 1717, a dividend was ordered at $7\frac{1}{2}$ per cent. and bank-bills continued to rise in value; whereas the state bills and bonds which had been given as security for debts contracted in the last years of Louis XIV. were declining.

Anquetil, who writes memoirs of the reign of that monarch, and the regency of the duke of Orleans, relates some curious circumstances respecting the early history of this bank, and the kind of traffic or gambling to which it gave rise. In addition to several grievances, the consequence of imprudent policy about this period, many families sustained loss by the depreciation of the state bills. According to him sixty-eight and a half was at one time lost on securities, while bank-bills rose 15 per cent. The treasurer received the former at $31\frac{1}{2}$ per cent. and delivered in payment the latter at 115. In this manner the public debts were discharged for a trifle, and the government carried on a gainful trade in paying them, though to the ruin of individuals, who were in fact pillaged of two-thirds of their property.

The anxiety to get rid of the discredited state-bills was vastly enhanced by a notion which was diligently propagated, that they would constantly fall in value till they were worth nothing; whereas on the contrary, the bank, supported as it was by a participation in the Mississippi trade and other extraordinary advantages, was sure to succeed, and materially enrich those who were concerned in it. A set of stock-jobbers now arose, who availed themselves of the occasional fluctuations between the two securities. When the state-bills fell low, these speculators purchased them in hopes of their rising, and immediately on their doing so, to however inconsiderable an amount, sold them for bank-bills. On the other hand, Bank.

when the latter appeared to be either stationary or to fall, these persons affected eagerness to possess government security; by which stratagem they were enabled to buy bank-stock at an under rate, though they were well aware that its credit would be speedily restored. Such alternations would often occur in the course of one day, and appear to have been skilfully managed. Law himself was not the least dexterous operator in these times, and in a short period amassed immense wealth, which naturally excited suspicion and jealousy. But he had a good friend in the regent, who protected him for some time against the decree of Parliament for his arrest.

When bank-bills became at length in less request, this ingenious projector invented a new expedient to raise their value. This was contriving to make money fall in value, by supporting the bank-crown at its original value. People were consequently induced to carry the former to the bank, in order to receive its bills in exchange, which were subject to no fluctuation. Government had by this time identified itself with the bank, and appears to have taken little care to obviate the serious and fraudulent measures by which its interests were attempted to be promoted.

All ranks of people were now seized with a kind of madness at sight of the immense fortunes which had been almost instantly made in the bank transactions. An individual commencing with a state-bill, was sometimes known, by exchanging it for silver, and that again for other bills, to realize some millions of livres in a few weeks. One street in Paris became noted as the resort of these traders, and the theatre of their operations. It was constantly thronged in such a manner, that several persons were crushed to death. But this calamity did not deter others, as any one who got firm footing in it was almost certain of making his fortune. Among the singular instances of this kind which occurred, is mentioned the fact of a certain deformed man, who in a short time gained more than 50,000 livres, by offering the hump on his back as a desk to such persons as had writings to sign!

But these favourable revolutions were the lot of comparatively few individuals. The general result was calamitous in the extreme. Trade and social intercourse ceased, the attention of every one being engaged to the price and variation of stocks; the hope of success dissolved every tie of honour, generosity, and friendship; the most sacred bonds of morality were completely broken; suicide, assassination, and all the crimes which avarice excites, followed in a train, and completed the catalogue of misery. An edict of the government on the 21st May 1720, reducing the bank-stock to one-half, interrupted the dream of opulence in which the public had indulged. This was said to have become necessary in consequence of the issue of paper much beyond what the bank could pay. It gave the death-blow to the whole system which Law had been erecting on the cupidity and ambition of the people. Notes fell in value, in spite of all the suggestions of his genius, and the influence of the regent's authority. Before the conclusion of the year, the bubble had entirely broken, and Law himself, narrowly escaping the violence of the populace, sought safety in flight.

Bankruptcy.

Second bank of France.—The New Bank of France was erected in 1803, on the consolidation of different banks, by an act of the government, which fixed its capital at something short of two millions Sterling, divided into 45,000 shares. The regulations for its management deserve every praise; and its prosperity, notwithstanding the critical condition in which this country has been frequently placed since its establishment, is the best criterion of the judgment and prudence displayed in its constitution. But it has necessarily met with difficulties.

A *run* was made on it for specie in 1805 and 1806, which at last occasioned it to suspend its cash-payments. In this last year a change took place in its administration, and its capital was doubled. The profitable disposal of the new shares, enabled it to recover and augment its operations.

The invasion of 1814 was a serious trial of its strength, as an immediate drain of its coin commenced. In the month of January of this year, it found it necessary to limit, though not to cease the payment in specie; and in the following month it was enabled to resume the issue of cash in full on demand, though the emergencies of the state, as is well known, were mightily magnified. The invasion which again took place in 1815, did not suspend cash-payments for a single day. So much for the fidelity of this establishment, in circumstances not to be parallelled in the history of any other country.

Banks of America.—The chief bank in America is that of the United States, established, in 1791, on a capital of ten millions of dollars. We know not any peculiarities in its constitution or history which merit notice. A new bank has lately been proposed at Philadelphia, in order to obviate the inconvenience experienced in that country from want of a uniform currency. Congress has given it encouragement, and the necessary capital has been subscribed for; a pretty general conviction of its necessity, and the commercial intelligence and ardour of the people, are the best guarantee of its benefits.

BANKRUPTCY, a state of insolvency, or the state of a trader's affairs when he is unable to discharge the just demands that are made upon him. In the early ages of society the laws and regulations of most states relative to insolvent persons, were severe and oppressive. Whatever might be the cause of his insolvency, whether from unavoidable misfortune, or culpable negligence in the management of his affairs, the debtor was regarded as a criminal, and the interest of the creditor only was consulted. But in the progress of civilization, and the extension of commercial affairs, the statutes and enactments on this subject took a wider range, and while the advantage of the creditor was not overlooked, the character and feelings of the unfortunate debtor were duly considered. The great object of the bankrupt laws of this country is to throw the whole property of the insolvent person into one fund for the benefit of his creditors, and to distribute this common fund by the most economical and speedy process, as far as it will go, in discharging the debts. The same general principles pervade the bankrupt laws of Scotland and England, but in many of the details and minuter parts the difference is considerable.

Bankrupt law of England.—According to the bankrupt law of England, traders only are subject to its operation. Persons of every other description are liable to the common law, and their effects may be attached by individual creditors. The marks of insolvency, or bankruptcy, are defined by the statute; as, when the debtor is inaccessible to his creditors, and cannot be seen or spoken to by them. The commission of any of the acts enumerated in the statute entitles a creditor, to a certain extent, to apply to the Lord Chancellor for a commission of bankruptcy. By this deed the estate of the insolvent person is vested in certain commissioners. As it may be granted without the bankrupt's knowledge, certain precautions must be observed to prevent improper and malicious applications.

It is the business of the commissioners to take proof of the bankruptcy, and of the debtor's being a trader, and to appoint three meetings by public advertisement. At these meetings the debts are proved, assignees are chosen, and the bankrupt must surrender himself, and, under pain of death, conform to the statutes. The bankrupt, and those connected with him, are to be examined by the commissioners on the state of his affairs; and if their answers appear to be ambiguous or evasive, the commissioners have the power of committing them to prison till they give a satisfactory explanation.

The estate of the bankrupt is now vested in the assignees, and when they have recovered all they can, they are required, after four months, and within twelve, to give notice of a meeting for a dividend, which the commissioners then direct to be made. Within eighteen months from the time of issuing the commission, a second and final dividend is ordered; and the surplus funds, after payment of the debts, belong to the bankrupt.

The bankrupt having conformed in all respects to the statutes, and the creditors, or four-fifths of them in number and value, having signed a certificate to that purpose, the commissioners are required to transmit it to the Lord Chancellor, who, upon a declaration on oath by the bankrupt that it was obtained without fraudulent means, may either allow the same or disallow it on cause being shewn by any of the creditors. If it be allowed, the bankrupt is entitled to a certain portion of his effects to assist him in recommencing business. The amount of this allowance is proportioned to the dividend on his estate, but it must never exceed L.300. By the certificate the bankrupt is also relieved from all claims for any debts which were either proved or might have been proved under the commission.—*Cooke on the Bankrupt Law of England.*

Bankrupt Law of Scotland.—By the bankrupt law of Scotland, all persons who are engaged in trade for themselves, or as agents or factors for others, or all persons who are capable of entering into trade, are liable to the process of sequestration. But holders of India stock, or stock in any chartered bank, in the Friendly Insurance Company, the Forth and Clyde, or other inland navigation, or in the British Fisheries, labourers who work for hire, landholders, and husbandmen, are excepted; and a foreigner who has traded to Scotland, or a Scotsman domiciled abroad, is not subject to sequestration.

The assent, or acknowledgment of the insolvency by the debtor himself, is admitted as a proof of bankruptcy, and supersedes other evidence. But without this concurrence certain previous processes are necessary, and the creditor, before sequestration can be granted, must shew that such have been pursued; as diligence by horning and caption for debt, imprisonment, retiring to a sanctuary, or absconding, or defending his person by force; or being out of Scotland, and not liable to be imprisoned, by reason of privilege or personal protection, and at the same time under diligence by charge of horning, attended with arrestment, or poinding any part of his moveables; or decree of adjudication for any part of his estate, either for payment or security of debt, at the instance of a creditor.

A person being bankrupt, one creditor to the amount of L.100, or two creditors to the amount of L.150, or three or more to the amount of L.200, either with or without the concurrence of the bankrupt, may apply for a sequestration to the Court of Session by summary petition. With the concurrence of the bankrupt, sequestration is immediately granted; but if this assent be refused, he is served with the petition, and if he decline to appear, the sequestration is allowed. The creditors are appointed to meet, and choose an interim factor for the management of the estate, and at the second meeting to nominate a trustee. The factor takes possession of the whole estate of the bankrupt, and the latter is bound to grant powers of attorney to recover any effects he may have abroad. The second meeting appointed by the Court must take place within six weeks, and not less than four weeks from the first deliverance on the petition; and at this meeting the creditors must produce the grounds of debt, with affidavits or oaths of verity; and at the same meeting the trustee is to be chosen by a majority of the creditors in number and value; the bankrupt must exhibit a state of his affairs, and the interim factor must present an account of his management.

The trustee having given security to the creditors for his faithful management, is confirmed in his appointment by the Court, and has the whole estate vested in him for behoof of the creditors. Within eight days of his nomination, the trustee must apply to the sheriff to fix two days for the examination of the bankrupt, and, if necessary, those concerned or connected with him. After the last examination, a general meeting of the creditors is held, at which three commissioners are chosen to superintend the management of the trustee.

The trustee is bound to keep regular accounts, and to lodge the money recovered in a bank; and at the end of twelve months a dividend shall take place to those creditors who have established their debts; at the end of eighteen months a second dividend, and at the end of every six months till the whole funds are paid up. But at the end of eighteen months from the sequestration, four-fifths of the creditors may order the whole concern to be brought to a close, by the sale of the outstanding debts, and making a final division.

With concurrence of the trustee and four-fifths of the creditors, the bankrupt may apply to the Court, after the second dividend, for a final discharge of all debts contracted before the sequestration; and if no valid objection be offered, such discharge is granted. After the second examination, the bankrupt has it in his power, by the statute, to offer a composition; and if this offer shall be approved by nine-tenths of the creditors, another meeting is called to consider it; and if nine-tenths still approve, and the Court, to whom the report is presented, pronounce it reasonable, the proceedings in the sequestration are closed, and the bankrupt is discharged, on giving satisfactory security for the payment of the composition.—Such were the general enactments of the bankrupt law of Scotland previously to 1816, when some alterations were introduced by an act of Parliament passed in that year, of which the following is a sketch.

1st, Trustees who fail to deposit the funds in bank, in violation of the act, are in future to forfeit to the estate a penalty of 20 per cent. on the amount, instead of $7\frac{1}{2}$ per cent. as was provided by the former act.

2d, The funds of the estate are not to be deposited in any bank where the factor or trustee shall be an acting partner, manager, or cashier.

3d, The commissioners are to meet periodically, (once in three months at least,) to examine the trustee's accounts, and to see that the funds are duly deposited in the bank, and that none are drawn out of it but for the purposes of the estate.

4th, Previously to the meeting when the commissioners are chosen, and when a composition may be offered, the trustee is to make out a full state of the bankrupt's affairs, with a valuation or appraisement of what the estate is worth, that the creditors may be enabled to judge of the fairness of the offer.

5th, The commissioners may at any time make out reports to the creditors, that they may know how the affairs are managed by the trustee.

6th, Notice of the bankruptcy—of the meetings for electing factor and trustee—of compositions—of the payments of dividends—and of the trustees application for a discharge, are to be inserted both in the Edinburgh and London Gazette.

7th, Printed notices are to be sent to every creditor who has claimed, of the payment of dividends and of the offer of a composition.

8th, Creditors who hold securities are to deduct their value in voting, and only to vote on the balance of their debt so far as uncovered.

9th, The trustee is not to be discharged by the court, without first calling a general meeting of the creditors, and having his accounts audited.

10th, At the end of three years the trustee is to make up a state of the affairs (if not wound up before), and also of the unclaimed dividends, and to call a general meeting of the creditors to receive instructions as to the final close of the sequestration.

11th, A printed report of the affairs is to be made out at the close of the sequestration, and distributed to the creditors for their satisfaction.

12th, Current sequestrations are to be proceeded in according to this act, so far as it does not interfere with the proceedings already had; so that any sequestration which has been pending for above three years may now be brought to a conclusion, and all unclaimed dividends accounted for to the creditors.

13th, The factor, commissioners, and trustee, are appointed by the creditors, as by the former act; and the duration of the law is for seven years.

BANK, SAVINGS, an institution which has been recently established in various parts of Britain, for the purpose of affording interest for small sums of money, which could not be conveniently deposited in banks according to the ordinary method of transacting their business.—See INSTITUTION, *Economical*.

BANKSIA, a genus of plants belonging to the Tetrandria class, and intended to commemorate the name of Sir Joseph Banks, in consideration of his exertions in promoting natural knowledge.

BANNERETS, an order of knights, who led their vassals to battle under their own flag or banner, by which they were distinguished from knights bachelors, who fought under the banner of another. The name is derived from banner, which signifies a *square flag*; for when this honour was conferred, the knight approached the monarch with his pennon in his hand, and, having reached the royal presence, the king commanded the ends of the pennon to be cut off, so that it was converted into a square flag or banner. Knights-bannerets were next in dignity to barons; the honour was usually conferred on the field of battle as the reward of personal bravery, but it was not hereditary. Sir John Smith, who rescued the royal standard from the rebels, was invested with this honour by Charles I. after the battle of Edgehill, and he is said to be the last who was formally created a knight-banneret; but after the battle of Camperdown, so glorious to the British fleet, under Lord Duncan, his Majesty's intention of conferring that honour on his lordship's flag-captain, and another officer, on board their own ships, when the fleet arrived in the mouth of the Thames, was frustrated by indisposition; but though the formal investment did not take place, the title and honours were granted and enjoyed by the individuals for whom they were intended.

BANTAM, a sea-port town of the island of Java in the East Indies, the capital of a kingdom of the same name, and a place of considerable trade before it was monopolized by the Dutch. Pepper was the chief commodity of this trade, and it is said that the annual exportation amounted to three millions of pounds. See JAVA.

BANTRY BAY, called also BEERHAVEN, a spacious bay in the county of Cork, and on the south-west coast of Ireland, is about twenty-five miles long, and varies in breadth from three to five miles, and is capable of admitting and affording shelter and safe anchorage to any number or magnitude of ships. In 1689, the French fleet which brought arms and ammunition to James II. was attacked in this bay by the British admiral, and, in 1796, a French fleet arrived in it with troops for the purpose of invading Ireland; but being either disappointed of co-operation, and thus discouraged to make the attempt, or being disabled by the storms which they had experienced in the passage, the fleet soon after left the coast.

BANYAN TREE. See BANIAN.

BAOBAB, the trivial name of the African calabash tree, a species of Adansonia in the Linnean classification. The trunk of the tree, which rarely exceeds 12 feet in height, acquires an immense thickness; the branches extend horizontally, or rather in a pendent form to a great distance, and become a close mass of foliage not less than 100 feet in diameter.

BAPTISM, from the Greek, and signifying *dipping in water*, is the rite or sacrament by which a person is admitted a member of the Christian church. Various opinions have been held concerning the origin of baptism, whether it is to be sought for among the Jewish ceremonies, or commenced with the mission of John the Baptist,—of the manner in which it ought to be practised, whether by immersion, as is supposed to have been the case in the time of the apostles, or by sprinkling, the mode adopted by many churches,—of the end and design of baptism,—of the time and place of performing this religious rite,---and of the proper subjects to whom it ought to be administered, whether infants ought to be admitted, or persons only who are capable of understanding its meaning and objects. The ceremony of baptism is regarded by some sects of Christians as forming no part of the religious ordinances of the gospel. The Quakers maintain, that it was intended for the Jews on account of their prejudices, or, having a reference to the mystical purification of the soul, that it was only requisite to be practised at the first introduction of Christianity. The forms and ceremonies observed in the administration of baptism, have been different at different periods, and in different churches; and some diversity of opinion has prevailed with regard to the persons who should celebrate that rite,—whether the commission to baptise is limited to the professed ministers of the gospel, or whether, in certain cases, it has not been extended to laymen, and even to women. Bingham *Origines Ecclesiasticæ*. Mosheim *Church Hist.* Robinson's *History of Baptism.*

BAPTISTERY, a place in which water appropriated to the administration of baptism is kept. The first edifices destined to this purpose were erected, it is supposed, about the middle of the third century; they were originally at a distance from the churches; and it is said that the first example of a baptistery connected with a church, was that which was erected in 496, adjoining to the cathedral of Rheims, for the baptism of Clovis, king of France, who had been converted by his queen. Some of these buildings were elegant structures; they were usually of an octagonal form, with a cupola supported by eight pillars; in the middle was a large hall for the priests and attendants; and a bath, corresponding with the form of the building, occupied the centre of the hall. The inside of the cupola was sometimes richly decorated with Mosaic work and emblematical representations. Fonts for the baptism of children were afterwards erected in these edifices: and some of these fonts, which were afterwards introduced into churches, remain to this day splendid ornaments of the cathedral churches of England and of the continent.

BAPTISTS, a body of protestant dissenters, who are mentioned in ecclesiastical history under various designations, borrowed either from the names of their respective leaders, or from their peculiar tenets with regard to the subject and mode of baptism. But that of anabaptists, by which they have been most generally known, both in Britain and on the continent, they now consider as a term of reproach, and think that, in fairness, it should no longer be applied to them as their appropriate appellation.

Historians are not agreed as to the period from which the baptists date their origin; some tracing it to the *sixteenth*, some to the *twelfth*, and some even to the *first* century of the Christian era. It seems certain, however, that they had no existence as a sect before they separated from the Lutherans in Germany about the time of the Reformation. During the struggles for religious liberty in that country, several of them came over to England, where they propagated their opinions, and where, according to Messrs Bogue and Bennet, they broke off from the independents in 1608, and constituted themselves a distinct congregation. From the reign of Henry VIII. inclusive, to that of James II. who issued a proclamation of indulgence to all non-conformists, they were, with little intermission, subjected to imprisonment, banishment, and death. In 1620 many of them emigrated into New England, where, notwithstanding the opposition with which they had to contend on their first settlement, they have so amazingly increased, that, by a late computation, they are estimated at 255,670 members in the United States alone. The earliest baptist society in Scotland, it would appear, was composed of soldiers in Cromwell's army; but it was not until 1765 that this denomination of Christians assumed in North Britain an organised and permanent form. Their success since has been very considerable; they amounted some years ago to 15 churches, besides smaller associations, and their number has been recently augmented by the accession of a few congregations, from what has been called the tabernacle connexion.

The baptists maintain, that there is neither precept nor example in the New Testament to warrant the baptism of any but such as have previously professed their faith in Christ. And indeed they consider this restriction as obviously implied in our Lord's commission to his apostles: "Go ye into all the world, and preach the gospel to every creature: he that believeth and is baptised shall be saved." Hence they conclude, that as infants are incapable of exercising the principle which is here required, they are altogether unfit for receiving the ordinance; and this conclusion, they think, is corroborated by the universal practice of the primitive church. Nor can this ordinance, they contend, be duly administered, without the immersion of the *whole* body, a truth which, they allege, is clearly established by the usage of the first Christians, and by the proper and literal meaning of the original term which expresses the action. Formerly they baptised their candidates in lakes, rivers,

&c. but now they generally employ baptisteries for the purpose. The Mennonites in Pennsylvania differ from most of the British and foreign baptists with regard to the *mode* of baptism; for although they admit none but adults to this privilege, they perform the rite while the person is in a kneeling posture, by the affusion of water on his head.

In the constitution and government of their churches, the baptists are strictly *congregational;* or, in other words, each church is held to be complete in itself, and not amenable to any distinct ecclesiastical court for the management of its concerns. From a disagreement among them in reference to certain points of doctrine, they have been divided into GENERAL and PARTICULAR. Some of both classes allow of free or mixed communion, that is, they judge it lawful to sit down at the Lord's table with those who have not been baptised by immersion on the profession of their faith; and some are Sabbatarians, who observe the *seventh* day of the week, or Jewish Sabbath, although these are few in number, and confined chiefly to America.

The *general* baptists adopt the Armenian system, and hold the system of general redemption. They are distinguished into what are termed the Old and the New Connexion: those of the former have, by verging towards Socinianism, greatly diminished; whereas those of the latter, who adhere to the principles on which they set out, are in a more flourishing condition, having about *seventy* churches in England. The *Particular* baptists, who again embrace the doctrine of particular redemption, and indeed all the articles of the Calvinistic Creed, are by far the most numerous, both at home and abroad. In 1798, they had, according to Dr Rippon, 445 congregations in England and Wales.

Among the SCOTTISH BAPTISTS, such of the brethren as are deemed qualified are requested to pray and exhort. But, in distinction from these, they have a plurality of elders in each church, whose peculiar province it is to labour in word and doctrine, and to preside in all cases of discipline, which, however, are not decided without the consent of the whole society. Every Lord's day they administer the sacrament of the supper, and contribute to the support of the poor. The inspired volume is the only standard of faith and practice which they acknowledge; and they receive none into their communion who does not so understand the doctrines which it unfolds, as, in all essential points, to enter into the views which they entertain. Considering mutual affection as a distinguishing badge of the Christian profession, they, on some occasions, express this sentiment by love-feasts, and the kiss of charity. Some diversity of opinion has arisen among the Scotch Baptists on various points of doctrine and discipline, in consequence of which, some churches are separate and independent, and hold no fellowship with each other, or with their parent institutions. Some begin to think that the Lord's Supper is not exclusively a church ordinance, and that it may be dispensed by two or three persons in private, none of whom is invested with the pastoral office.

BAR SUR ORNAIN, formerly Bar le Duc, is the principal town of the department of the Meuse in France, and includes a population of 8000. The trade in wood, wines of an excellent quality, and hemp, is considerable, and is greatly facilitated by means of water-carriage to Paris.

BARATIERE, PHILIP, an extraordinary example of the early evolution of the intellectual powers, was the son of the minister of the French church at Swobach, near Nuremberg, and was born in 1725. In his fourth year he could converse in Latin, French, and High Dutch; and before he had reached his sixth year he was qualified to read the Old and New Testament in Greek, and at the same time had made some progress in the Hebrew language. The perusal of the Greek fathers and the Rabbinical writers occupied much of his time when he was only ten years of age; but between that period and his fifteenth year, his attention was occasionally directed to physical investigations; particularly to astronomy, and a method of discovering the longitude, which was communicated to some learned societies. To the liberality of the Margrave of Brandenburg-Anspach he was indebted for a pension and the use of his library; and to the university of Halle for the honorary degree of master of arts. During the remaining part of his short life, he was alternately engaged in metaphysical inquiries, antiquarian researches, and experimental philosophy. But this intellectual prodigy was connected with a feeble frame, which severe study had in no small degree contributed to exhaust and undermine before he had completed his twentieth year. He died in 1740.

BARBADOES, an island of the West Indies belonging to Britain, and the most easterly of all the Caribbæan islands, lies in north latitude 13° 10′, and west longitude 57°, is about 25 miles in length and 14 miles in breadth, and includes an area of nearly 105,000 acres. The surface of this island is not greatly diversified with hills and vallies; it is watered with several small streams, and has some springs of good water; but the supply seems not sufficient to preclude the use of reservoirs for collecting the rain water. The temperature of Barbadoes is pretty uniform, and the climate is found to be more salubrious than most of the West India islands. The soil, reposing on calcareous strata, containing animal remains, is various,—as black mould, reckoned the richest and most productive,—a whitish grey mould, in which clay predominates,—and a reddish earth, which is considered of inferior quality.

The first discovery of Barbadoes is ascribed to the Portuguese; it was then uninhabited, and they attempted no settlement. It was visited by an English ship early in the 17th century; but no permanent settlement was made till 1624, when a few adventurers from England established themselves, and, during the civil wars which soon after distracted the kingdom, received a great accession to their numbers,—so great indeed that, in 1676, it is said that the white population was 50,000, and that of the slaves amounted to 100,000; but this is undoubtedly a most erroneous statement.

The white inhabitants, in 1786, were numbered at 16,167, and the slaves at 62,953; but the latter were estimated, in 1753, at neary 70,000. In 1811, the whole population was stated as follows: Whites

Barbarossa. 15,794; free persons of colour 2613; and slaves 69,132, making the total amount equal to 87,539. Barbadoes is divided into eleven parishes; and Bridgetown, Charlestown, St James's, and Speights, are the only towns of the island. Bridgetown is the capital, and the seat of government. The political constitution of the island, with some slight deviations, is analagous to that of the other British West India colonies. Beside the established clergymen of the church of England in each parish, the Methodists and Moravians have small congregations, chiefly composed of negroes; and the congregation of Jews, in 1811, amounted to about one hundred persons.

The soil and climate of Barbadoes are favourable to the growth of all the plants of tropical regions. But sugar, rum, ginger, cotton, and aloes, may be regarded as the staple vegetable productions, and constitute the principal exports of the island. In 1736, the crop of sugar was estimated at 19,000 hogsheads; in 1789 and 1790, it was reduced to 9000 and 10,000 hogsheads; but, in 1792, the exports from Barbadoes were, of sugar 17,000 hogsheads, of rum more than 5064 puncheons, of ginger 3046 bags, and of cotton 974,178 pounds, beside aloes. The total value of the exports, in 1787, exceeded L.539,000 Sterling. The imports from Britain, the British colonies, and the United States, consist of corn, flour, rice, salt beef and pork, butter, live-stock, timber, shingles, and staves.

Barbadoes has been visited with some severe calamities. Bridgetown was twice nearly consumed by destructive fires; and it had scarcely recovered from the effects of these terrible disasters, when a tremendous hurricane, in 1780, laid waste the island, rendered the capital a melancholy scene of desolation, and destroyed more than 4000 of the inhabitants, blacks and whites inclusive.

BARBAROSSA, Aruch, a celebrated corsair, who, from the humble station of the son of a potter in the Isle of Lesbos, rose to the sovereignty of Algiers, was born between 1470 and 1480; at the early age of thirteen joined a body of pirates, and in a short time so distinguished himself by his valour and enterprise that he was entrusted with the command of a fleet of twelve gallies and some smaller vessels, while his brother Hayradin was second in command. The appellation *Barbarossa* was derived from the redness of his beard. With this powerful armament they struck terror throughout the Mediterranean, and, in the insolence of their might, declared themselves the *friends of the sea, and the enemies of all who sailed upon it.* The King of Algiers applied to them for assistance against the Spaniards; and Aruch, the elder brother, having conducted 5000 men to Algiers, was received as a deliverer; but his ambition was tempted with the prospect of sovereign authority,—he murdered the king, and seized the sceptre. To this usurped dominion he soon after added the conquest of Tremecen. But the dread of his power, and the extent of his piracies, called forth the interference of the Emperor Charles V. who dispatched a body of troops to Africa, to dispossess him of his territory, in defence of which he was defeated and slain.

The affairs of Europe at this time sufficiently occupied the resources of the Spaniards, and thus left Hayradin to enter into the undisturbed possession of his brother's throne. He assumed the same name, extended his conquests, placed his dominions under the protection of the Grand Signior, Solyman the Magnificent, and obtained the command of the Turkish fleet. By artifice, and the murder of the young prince of Tunis, he succeeded in adding that state to his dominions; and after various exploits on the coasts of the Mediterranean, he died in 1547. Robertson's *History of Charles V.*

Barbary. BARBARY, or Barbary States, is the modern name of a large Mahometan country on the north coast of Africa, extending from the Atlantic ocean to the confines of Egypt, and comprehending the independent districts or states of Morocco and Fez, Algiers, Tunis, and Tripoli, together with a considerable, but little known tract between them and the great desert of Sahara. It stretches from the 10° W. to the 26° E. longitude, being about 2000 miles long, and from the 26° to the 37° N. latitude, of very irregular breadth. The Mediterranean sea forms its northern boundary. An almost perfect identity of climate, the similarity of vegetable and animal productions, and a striking correspondence in the features, manners, and institutions of the various inhabitants, properly constitute this one region; nor do the historical or political differences, by which the respective governments may be distinguished, claim any peculiar attention from the general reader.

Climate and seasons.—The climate, on the whole, is temperate, considering the geographical position; the vicinity of the Atlantic ocean and Mediterranean sea contributing powerfully, it is probable, to moderate the tendency to excessive heat. Rain is frequent during the winter months; less copious during spring; and rarely seen in summer, which is consequently both unpleasantly hot and often productive of very formidable diseases. Towards the end of August, in general, the temperature of the atmosphere becomes more moderate, and gradually falls during the succeeding autumn, which ends about November, when the winter, or rainy season, commences. In this last period, the mornings are usually sharp, and frost and snow are occasionally experienced; but these approaches towards cold are rarely either so rapid or so long continued as to compel the inhabitants to have recourse to artificial heat. The easterly winds, which prevail from May to September, are commonly dry, though the atmosphere be cloudy; westerly and northerly winds blow violently in March, and are loaded with moisture, which falls in showers during the intervals of the gales; the south and south-west winds of summer aggravate its evils by diffusing the noisome product of the sun-burnt desert.

Soil and vegetation.—The soil, like that of the African continent in general, is of a light, sandy consistence, so as to be very easily worked, which peculiarly suits the indolent habits of the people. The abundance of small streams which issue from the mountains, traversing the country, secures an amazing degree of fertility. A richer mould is met with in some of the vallies which divide the ridges of hills;

Barbary.

and in them, accordingly, vegetation is still more powerful and varied. In these happy spots are found some of the most delicious fruits and flowers; the pomegranate, the orange, the olive, the date-palm, the pistachia, the jasmine, the oleander, the white musk-rose, the bay, the myrtle, &c. Like the heathy districts of Spain, many of the rocky intervals between the vallies abound in cork-trees and oaks, under whose protection the luxuriance of nature has displayed itself in the production of lavender, sage, and many other aromatics. The arborescent broom, various species of cistus, the aloe, the sumach, the mignonette, of a large size, and probably perennial, several sorts of euphorbia and cactus, and many other plants, which are capable of heat and drought, ornament some of the rocky tracts, and yield nourishment and shelter to the wild goats which inhabit them. The moist and low lands have their full share of appropriate vegetation, saline succulent species, and bulbous rooted plants, a profusion of grasses, &c. Wheat and barley are a good deal cultivated; oats are less common, beans and lentils are abundant, as are also pot-herbs of such kinds as are usual in European countries.

Mountains and mineralogy.—The chief mountain range in this country has received the name of Atlas from classical times. It is nearly co-extensive with the length of Barbary, but is most elevated towards the western extremity, in part of which the height is said to be upwards of 13,000 feet above the level of the sea. Some of the eminences are almost perpetually covered with snow; the lower regions are either ornamented by natural vegetation, in the form of forests and a variety of shrubs, or are considered well worthy of cultivation from the richness of the soil. This Atlantæan chain is nearly intermediate between the plain of the Barbary states or the coast of the Mediterranean sea, and the sandy desert. A smaller range of mountains, still nearer the former, extends from the straits of Gibraltar to the boundary between Algiers and Tunis. The mineralogical constitution of these hills is very little known. It is conceived, that the chief elevations are of the primitive or first order of rocks; and according to Ali Bey, one of the latest travellers in this country, the rocks towards the coast are of granite, with superimposed sandstone. Marble and other calcareous strata are abundantly distributed through certain parts of the country. The metals are not plentiful, or, more correctly speaking, through the carelessness of the people, have not yet been discovered to any great amount. It is perfectly certain, that both gold and silver are to be met with in some districts; but the absurd policy of the sovereigns, particulary those of Morocco, has hitherto prevented the necessary mining operations.

The *rivers* of this region are numerous rather than large, the peculiarity of the country, and the shortness of the distance they have to run towards the ocean, rendering their junctions few and unimportant. The Malub, Malva, or Muluvia, one of the most considerable, divides Morocco from Algiers, which again is watered by the Shellif. This rises on the northern side of the Atlas, and runs in a westerly direction to the Mediterranean. It is the Chinala of antiquity. The chief river of Tunis is the Mejerda, in former times the Bagrada. Tripoli, which lies towards the east of Tunis, in consequence apparently of the diminished size of the mountains, or rather their total disappearance on the frontiers of Algiers and Tunis, is destitute of any river of note. Several lakes and marshes, with some curious saline and mineral springs, are interspersed through the country. The abundance of saline substances is manifested by the fact of the banks and beds of many of the rivers and lakes being encrusted with them during the summer months.

Barbary.

Animals—The zoology of this region is somewhat interesting. Of the larger quadrupeds, we find the panther, hyæna, wild-boar, and lion. The antelope, so noted for swiftness, is hunted, as well for the excellence of his flesh, as for the pleasure of the chace. Camels, horses, asses, cows, sheep, and goats, are all domesticated. The cattle are said to be small and slender; and the horses have degenerated from their long-boasted excellence. In some places the sheep are as tall as fallow-deer, but generally they do not attain to a great size. Among birds, the ostrich and stork are mentioned as numerous. The feathers of the former constitute a valuable commercial commodity. Game of various kinds is plentiful in Morocco, where also fowls and pigeons are abundant; but ducks are rare, and geese and turkeys unknown. Serpents exist of several species, and in great numbers. The gigantic *boa constrictor* is far from being a rare visitor of this region. It was to this species, no doubt, that enormous creature belonged, which appalled the whole army of Regulus on the banks of the Bagrada, and which, according to Pliny, was an hundred and twenty feet long. Specimens measuring thirty feet and more are not of rare occurrence in the museums of European naturalists. All the wild beasts together do not occasion so much mischief as one insect, the locust. This is properly a native of the desert, which, however, it is impelled, for some hitherto unexplained reason, to abandon at certain intervals, when it seeks those parts of the neighbouring countries where its food is to be had. Vegetation of every kind, notwithstanding the employment of all possible modes of annoyance and defence on the part of the inhabitants, is absolutely, and in an amazingly short time, consumed by the myriads of these insects on their portentous visitations. It is some consolation, in so grievous a calamity, that the locust itself presents a very palatable nourishment.

People—The inhabitants of Barbary are of several distinct races, of which the *Moors* are most numerous. These appear to be a mixed race descended from the ancient *Mauri*, as the name imports, but blended with the progeny of other people. They generally dwell in the cities of the coast, but are often found in places far inland, where they subsist on their flocks, and the produce of their wretched agriculture. The former usually carry on some trade, and have attained to no very contemptible degree of refinement in manners; but their propensity to pleasure, to jealousy and revenge, their superstition, ignorance, indolence and family pride, with an amazing gravity of deportment, are still more conspicuous features. The women, as is usual in Mahometan countries, where they are considered as merely subservient to the inclinations and caprices of the other sex, are cautiously secreted from public notice in the harams of their lords and masters. Each man is permitted to have four wives, and as many concubines. One of the wives is always superior to the rest, and is entitled to a display of authority and consequence to which none of the others can lay claim. Their days are not altogether consumed in silly gossip, the toil of decorating their persons, or administering to sensual enjoyments, as has often been imagined. On the contrary, they have various domestic duties to perform, and occasionally exhibit an industry and maternal solicitude which would honour the sex in any country.

The *Brebers*, *Berebbers*, or *Barbars*, from whom this region has been named, are dispersed over the whole country, of which, notwithstanding their misfortunes, and the repeated, or rather unintermitting attempts to subject them to the Moorish yoke, they consider themselves the proper owners. They are probably, indeed, the offspring of the original possessors, and have spirit and inclination enough, though they do not at present enjoy all the other requisite means, for realizing their pretensions. Their language is of high antiquity, and differs from all the other dialects spoken in this region; but its nature and connexions are not well understood. They are governed by their own chiefs, and still contrive to maintain a sullen and somewhat ominous independence in the fastnesses and obscurities of the mountains. The *Shelluhs* inhabiting the southern parts of Morocco, are in many respects similar to the Brebers, of whom they are, perhaps, a merely incidental branch.

Jews abound in Barbary, where, as usual in other countries, they addict themselves almost exclusively to the art of making money, and where, as was formerly the case throughout the whole of Europe, they pay dearly for their privilege and acquisitions, by inheriting universal contempt, and being perpetually liable to the most vexatious injustice and rapacity. By a very natural reaction of feeling, they become selfish, hypocritical, and cunning. Of late years, it is said, the number of Jews has greatly diminished, their fortitude and love of gain very probably giving way to such enormous oppression as they experienced.

The characteristics of the *Arab* are modified by the despotic nature of the governments established in Barbary, and probably by occasional intercourse with other people. But the change unfortunately is not to the better. Their almost chivalrous love of rapine has dwindled into contemptible thievishness; their courage, no longer secure and even honourable in its heroism, seeks the protection of night and of numbers; their sense of independence, in place of its former dignity, assumes a brutal ferociousness of manner; and a hospitality of conduct, which either obviated or redeemed their original vices, has been nearly totally immersed in the unmercifulness of religious bigotry.

The *Turks* resident in Barbary are noted for their idleness, indolence, and general depravity. A race of *negroes*, originally derived from the interior of Africa, and augmenting, in Morocco particularly, by the encouragement of the government, which employs it in its armies, is rapidly rising into distinction, and promises ere long to effect some important political changes.

It is almost unnecessary to mention, that the *Christians* who had the misfortune to reside in this country, were, with very inconsiderable exceptions, doomed to slavery, from which there was scarcely a possibility of being redeemed but by the renunciation of their religion, or the payment of exorbitant ransoms by their relatives. This reproach, it is hoped, under which Europe was for so many centuries degraded, has for ever been wiped away by the late vindictive and successful interference of our own country.

States.—Morocco, including *Fez*, has been nominally an empire since the fourteenth century. It is the most westerly, and the largest of the Barbary states. Judicious policy, and a liberal intercourse with foreign powers, are all that are wanting to secure its welfare and consequence. A population amounting, according to Mr Jackson, to upwards of 14 millions, and possessing the highest advantages of position and natural resources, must be ill guided, indeed, to have proved so ineffective in the drama of the western world. Its commerce has greatly declined through the absurd measures of the present emperor, Muley Soliman, who is nevertheless one of the most sensible and moderate sovereigns which Morocco has ever enjoyed. Mogadore is now the chief port. The principal cities are, Morocco, Fez, Mequinez, Tangier, and Sallee.

Algiers is next in rank and situation to Morocco. Its population, which is variously and very uncertainly reported, probably exceeds five millions. The famous Barbarossa seized this government about the commencement of the 16th century, sheltering himself under the protection of the Grand Signior, who henceforth became the nominal sovereign, but who, in reality, for a long time has possessed neither power nor influence in Algiers. Since that period, this state has been almost perpetually engaged in piracy, and has often excited the indignation of the European countries, all of whom, at some time or other, have suffered from a grievance which any one of them almost might singly have annihilated, had there existed no suspicion or conviction that the rest would interfere. Yet it is remarkable, that the expeditions which the superior means of the larger governments, at the times of their political ascendancy, enabled them to send against these robbers, have generally failed in immediately inflicting adequate retribution, and always in preventing a renewal of the atrocities complained of. Whatever success did attend these undertakings, was recompensed by a merely temporary exemption of the individual from the aggressions which occasioned them. This freedom, again, has been often purchased by vile compliances and degrading tribute; nor is there, perhaps, a single maritime state in Europe, capable *by any means* of obtaining a *safe-conduct*, which has not witnessed its neighbours exposed to pillage and captivity, with a malignant and dastardly satisfaction at its own escape. The recent conduct of Britain establishes her title to the championship of humanity and civilization;

and the 27th of August 1816 will ever be blazoned as the day of their triumph, through the bravery and good conduct of her sailors. But it is neither unmanly nor ungenerous to doubt, whether the enterprize of one day, however judicious and energetic, have broken the habits of ages, or determined a nation of ruffians to imitate the virtues by which they were overcome. Algiers is divided into provinces, in which particular it differs from Tunis, the state next to be mentioned. The chief of the government, which is a strict despotism, is denominated Dey, who generally resides in the town of Algiers. His revenue has been said to exceed L.120,000 a-year. He can bring into the field an army of more than L.50,000 men; but they are badly trained, and unless infuriated by religious hatred, can scarcely be said to possess any of the qualities of soldiers.

Tunis, which lies to the east of Algiers, is neither so large nor so populous, but it is probably better cultivated, and on the whole the inhabitants have more refinement, and greater liberality of disposition. These two states frequently carry on hostilities with each other; but their warfare is rather of a ludicrous nature, and seldom occasions bloodshed, a mutual and highly operative dislike to hard blows commonly preserving a very expedient distance between them. The troops of both, however, are astonishingly expert in pillaging the undefended, and "slaying the slain." Their dexterity in these valourous arts is on the whole so equal, that no advantage remains long with either party; and as success is consequently pretty regularly alternate, and of course always merits rejoicing, it seems that their rencontres are very conducive to social happiness! The sovereign of Tunis is called Bey, and acknowledges the Grand Signior as his superior.

Tripoli is a still smaller state, of which less information is possessed by Europeans than of any other in this region. It has long been almost altogether under Turkish government, a sufficient reason for its inferiority and obscure condition; but a late bashaw, as its chief is styled, partly threw off the yoke, and adopted some judicious measures, which might have ensured prosperity had his successor profited by his example.

BARBER, from *barba* the beard; a person whose profession it is to shave the beard of others. Several centuries elapsed before barbers were known in Rome as a separate trade; and when the constitution of civil society began to be settled and improved in Europe, it appears that they were united with the corporation of surgeons in most countries. The practice which barbers had acquired in handling delicate instruments probably led to this union. The barbers of London were incorporated with the surgeons in the time of Henry VIII.; and it was not till the reign of George II. that the separation took place. The origin and meaning of the barber's pole, a white staff, ornamented with a coloured spiral band, have been the subject of much discussion. The most natural explanation seems to be, that it alludes to the surgical department of the united profession, that the pole is a representation of the staff grasped by the patient in blood-letting to increase the flow of blood by the action of the muscles, and the band denotes the ribband or fillet for binding up the arm.

BARBOUR, John, one of the earliest Scottish poets, flourished in the 14th century, and died near its close in 1396. He seems to have been a person of some consideration; he was archdeacon of Aberdeen; was engaged in important missions to England and France; and had a pension from government, either for his public services or as a reward for his literary labours. The only production which has transmitted his name to posterity is a historical poem, entitled, "The Acts and Life of the most victorious Conqueror Robert Bruce, king of Scotland," &c.; the best edition of which was published in 1790, in 3 vols. 8vo.

BARBUDA, one of the Caribbee islands in the West Indies, about 20 miles long and twelve miles broad, contains a population of nearly 1500, and supplies the neighbouring islands with live-stock and Indian corn, for the rearing and culture of which the soil seems best suited.

BARCA, an extensive region of Africa, which stretches along the shores of the Mediterranean from the confines of Egypt to the territory of Tripoli, and is bounded on the south by the Sahara or Great Desert. Excepting a few spots near the towns and villages, where the verdure of vegetation appears, the whole of this immense tract is a barren, sandy waste, without water, and without the means of cultivation. These verdant spots are called *oases* or islands. Of the interior of Barca little is known. The natives of the maritime towns, in their general character, resemble the inhabitants of Barbary. They profess the Mahometan religion; regard themselves under the protection of the Porte; but are tributary to the bashaw of Egypt or Tripoli. The inland districts are inhabited by wandering tribes of Arabs, who live chiefly by plunder. Millet, maize, or Indian corn, and dates, are the only vegetable productions which occupy the industry of the inhabitants on the fertile spots. Brown's *Travels*. Horneman's *Travels in Africa*.

BARCELONA, the capital of the province of Catalonia in Spain, stands on a fertile plain encompassed on one side by hills and bounded by the Mediterranean on the other. Few cities can boast of higher antiquity; it traces its origin to the Carthaginians, 250 years before the Christian era; and having successively acknowledged the authority of the Romans, the Goths, and the Moors, after a tedious and disastrous siege of seventeen months, yielded to the French arms in the beginning of the 9th century. But in the year 985 it was taken by the Moors, who destroyed the city by fire, and doomed a large proportion of the inhabitants to slavery. After this period of its history, Barcelona has been the scene of many severe struggles during the political revolutions of Spain and of Europe; but in 1714, when it refused to join in the allegiance to Philip the Fifth, declared by Catalonia and the contiguous provinces, in consequence of the treaty of Utrecht, in the preceding year, it sustained one of the most memorable sieges recorded in history.

Barcelona is strongly fortified with walls, furnished with numerous bastions, a citadel and a fort on an elevated spot. The ramparts form a spacious terrace, which commands a fine view of the town and surrounding territory. The streets are generally narrow and irregular, yet some of them are spacious and elegant; many of the public buildings are fine edifices, and the cathedral is a magnificent structure. Barcelona had once a university, which has been suppressed; and four academies, in which natural philosophy, history, jurisprudence, are taught, are its only institutions for literature and science. The harbour is spacious and well sheltered, and admits, sometimes, more than a thousand vessels in the course of a year. A bar, formed by the rivers Bezos and Llobregat, where they discharge their waters into the sea, renders the approach to the harbour difficult, and sometimes not altogether free from danger.

The population of Barcelona, including Barcelonetta, a new town in its vicinity, was estimated in 1806 at 160,000. Manufactures have long flourished; and printed cottons, silks, satins, velvet, lace, gold and silver embroideries, stained-paper, hat-making, glass-making, and a foundery for cannon, give extensive employment to the inhabitants. More than 10,000 persons are occupied in spinning and weaving cotton, which commenced about the year 1790. The trade of Barcelona is extensive and lucrative, and no town in Spain enjoys more commercial intercourse with the different states of Europe and with the Spanish colonies in America. Its annual value has been stated at the enormous sum of a million and a half Sterling.

Some beautiful remains of Roman antiquity are still visible; among which are enumerated part of a Mosaic pavement, composed of white and blue stones, representing tritons and fishes; a magnificent arch of an aquæduct; a white marble basin elegantly sculptured; six massy fluted columns with Corinthian capitals; and a small statue of Bacchus, of exquisite workmanship. Laborde's *Spain*, Vol. I.

BARCLAY, John, a literary character of considerable eminence in the beginning of the 17th century, was born in France about the year 1582. His father, a native of Aberdeenshire in Scotland, had resided long in France, and was professor of civil law in the university of Angers. It would appear that he had been educated among the Jesuits, for he was strongly urged to enter into that order; but his father resisted their solicitations, and, about the time of the accession of James I. to the throne of England, he brought him to that country, where he composed and published a Latin poem on the king's coronation. From this time, London, Paris, and Rome, where he died in 1621, were at different times the place of his residence. He was the author of various works; but he is best known by the *Argenis*, a kind of political romance, which is greatly distinguished by the elegance of its Latinity.

BARCLAY, Robert, the celebrated author of the *Apology* for the Quakers, was born in 1648, and descended from the family of Ury in Aberdeenshire, which could trace a line of ancestry for several centuries. His education was conducted partly in his native country, and partly at the Scots college in Paris, in which his uncle held the place of rector, where he gave early proofs of the superiority of his intellectual powers, and especially of that acuteness of judgment and promptitude of reply so requisite in the public disputations, which formed a considerable part of the prevailing system of tuition.

The dread which his mother entertained of his conversion to the church of Rome occasioned his recal to Scotland; a short time only elapsed when he joined the society of Quakers; and not long afterwards he appeared as an author in defence of the system and society which he had adopted. Beside other works, an exposition of the principles of the society, under the title of *A Catechism and Confession of Faith*, appeared in 1673, and was soon followed by his *Theses Theologicæ*, or "Theological Propositions."

About the year 1676, he accompanied the celebrated William Penn, the proprietor and settler of the province of Pennsylvania in North America, in a tour through England, Holland, and Germany; and in the same year the *Apology for true Christian Divinity*, written in Latin, was published at Amsterdam, was soon afterwards translated into six different languages, and obtained a very extensive circulation, while it became the subject of much controversial discussion. Towards the close of this year, after his return to Scotland, he suffered five months imprisonment at Aberdeen, along with other members of the society, in consequence of the severe edicts of the times against non-conformists. The remaining part of his life was occupied in frequent journies to England on the concerns of the society; he was much in favour with Charles II. and his successor the Duke of York, and was frequently admitted to personal, and seemingly familiar, conferences with both monarchs. The commission which he had received, as governor of East Jersey in America, was confirmed to him by the former for life, with power to appoint a deputy to discharge the duties of the office. During his last visit to London, in November 1688, a period so fatal to the fortunes of James II. he had a friendly interview with that misguided monarch on the eve of his exile. Having spent two years of retirement at his patrimonial residence, and after attending a meeting of the society at Aberdeen, he was seized with a fever on his return to Ury, and died in October 1690.

Robert Barclay possessed a vigorous and active mind, which was highly improved by the regular discipline of a classical education. His numerous works bear undoubted marks of deep and careful research, and of various and extensive learning; and the equanimity of his temper, the vivacity of his disposition, and the benevolence of his heart, were not less conspicuous than his powerful intellectual acquirements.

BARD, which is said to be derived from a British or Celtic word, and signifies a *singer*, was a poet and musician by profession, in ancient times, who celebrated the heroic deeds of his countrymen, or poured forth the wail of lamentation when disaster befel the warrior or the nation. In those periods of society which precede the knowledge of letters and the art of writing, bards are to be regarded as the traditionary historians of the age; and hence it appears that, among all nations, those who were qualified to devote themselves to the profession were liberally supported and warmly cherished. The requisite talents to attain excellence in the art, a musical voice and ear, skill in instrumental music, and a genius for poetry, are seldom united in the same individual; so that he who was possessed of the rare assemblage of the powers of music and of song could not fail to share largely in the esteem and regard of his admiring countrymen.

The early history of all nations alludes to bards; they were common among the Greeks in the days of Hesiod; Homer refers to persons of the same profession; and at the feasts of the ancient Romans they were employed to celebrate the achievements of their heroes and great men. Even among the ruder nations of modern times, as among the natives of Mexico and Peru, the bards sing the praises of their chiefs and warriors. But in no nation has this profession assumed so regular and systematic a form as among the Gauls or Celtic tribes. The institution of druids and of bards was equally regarded as an essential part of their manners and policy. The first were the philosophers of the age and the priests of religion; and it was the business of the last to recite and record the deeds of heroism and of fame, to be transmitted in song to future times.

A numerous band of bards was kept in the train of kings, princes, and great men. They were divided into classes and orders. To the chief bard was assigned a certain number of inferior character; and even the latter were attended by others still less distinguished than themselves. In Ireland, Wales, and the Highlands of Scotland, the bards, from obvious causes, flourished longer than in any other part of the British dominions; but as civilization advanced, and letters were cultivated, they gradually degenerated into the less respected profession of harpers and minstrels; and in Wales, in the time of Queen Elizabeth, they had become so numerous and burdensome to the inhabitants, that the interference of the legislature was required, and a statute was expressly enacted for their regulation and partial suppression. Warton's *History of English Poetry*. Blair's *Dissertation* prefixed to *Ossian's Poems*.

BAREGES, a village in the department of the Upper Pyrenees in France, famous for its hot springs, which have long attracted crowds for the purpose of drinking and bathing. The village consists of a single street of indifferent houses; and some years ago no inn for the accommodation of the traveller had been established. The surrounding mountains, which are composed of primitive rocks, are clothed with verdure to their summits; but no woods break the dull uniformity of their aspect. The mountain strawberry is so abundant, that during the summer months, it furnishes an essential and an agreeable part of the dessert at the tables of the visitors.

The waters of Bareges have their origin in several sources, varying in temperature from 94° to 114° Fahrenheit, and commodiously distributed into four separate baths; they are quite limpid when they are received into the bathing troughs, and are of a sulphureous and saline quality. Muirhead's *Travels*, p. 302.

BAREITH, a city of Franconia in Germany. See BAYREUTH.

BARFLEUR, a town of Normandy, now the department of the Channel in France, famous as the seaport from which William the Conqueror sailed when he invaded England. The Cape of the same name is 12 miles east of Cherburg.

BARI, a province of Naples, which includes a square area of nearly 700,000 acres, and a population exceeding 280,000, and produces corn, saffron, fruits, and cotton. Bari, the ancient *Barium*, is a sea-port town on the shores of the Adriatic. The number of inhabitants is vaguely stated by different travellers from 6000 to 30,000, who are occupied chiefly in the manufacture of glass, cotton, and linen, and fishing. Bari is 120 miles north-east from Naples.

BARILLA, sometimes signifying the plant from which the soda of commerce is obtained, but more commonly the alkali itself, is extensively cultivated on the salt-marshes of Spain which stretch along the shores of the Mediterranean. The preparation of the barilla, or soda, is conducted nearly in the same way as the kelp manufacture of this country.

BARK, the external covering of trees, which is of very extensive use in the arts, as the bark of the oak employed in tanning, of the alder and walnut tree in dyeing, of the cinnamon tree in spicery, of the cinchona or Peruvian bark tree in medicine, and of a species of oak for corks. Ropes, cloth, and paper, are also manufactured from the bark of different trees, examples of which are well known in the curious fabrics of the South sea islanders.

BARLEY, the English name of the genus *hordeum*, several species of which are objects of culture. See AGRICULTURE.

BARNES, JOSHUA, a learned critic and editor, was born in London in 1654, educated at Cambridge, was elected a fellow of his college, and appointed professor of Greek in the same university. Before he had reached his 17th year, he appeared as the author of a collection of Latin and English poems. But he was more distinguished as an editor; and the works of Euripides, Anacreon, and Homer, were successively the subjects of his learned labour and critical skill, and are still valued by classical scholars. He died in 1712.

BARNSLEY, a town of the West Riding of Yorkshire in England, with a population approaching to 4000. Iron wire, nails, and various kinds of hardware, cloths and glass, are thriving manufactures, which the abundance of coal, iron ore, and timber in the surrounding country, and the advantage of inland navigation, have greatly improved and extended.

BARNSTAPLE, a sea-port town of Devonshire in England, stands in a fine vale on the banks of the Taw, is noted for its manufactures of baize, silk stockings, and waistcoat pieces, and had formerly some trade; but the approach to the harbour is greatly impeded by sand banks. Barnstaple was once defended by walls and a castle. The population in 1801 amounted to 3748.

BAROMETER, from two Greek words signifying *weight* and *measure*, is an instrument for measuring the weight or pressure of the atmosphere; and as it distinctly indicates the changes that take place in the weight of that elastic fluid, the coincident changes of the weather being observed, this instrument has been employed to denote those changes, and in this application is well known under the name of the *weather-glass*. The barometer is also in use for ascertaining the height of mountains, on the principle, that the higher in the atmosphere the instrument is carried, the pressure is proportionally diminished, by the action of a shorter column of air. For the principles of its construction and application, see METEOROLOGY and PNEUMATICS.

BARON, a title of rank applied to a person who holds a barony, or who possesses the right, by letters patent, of being a member of the House of Lords. See RANKS, *Distinction* of, under HERALDRY.

BARONET, a title or dignity next to that of a baron, and taking precedence of all knights, excepting knights of the garter and knights-bannerets. The order of knights-baronets was instituted in 1611 by James I. and the number was then limited to 200, but has been since indefinitely extended at the king's pleasure. See RANKS, *Distinction* of, under HERALDRY.

BARONETS of Scotland, or of Nova Scotia, was an institution proposed by James I. but not completed till 1625, in the time of his successor, for the express purpose of encouraging the settlement and cultivation of Acadia, or New Scotland, in North America, which was occupied by the English. To each adventurer a portion of land, with many privileges, was granted. See RANKS, under HERALDRY.

The institution of the order of baronets in Ireland, with privileges similar to those in England, took place in the 18th year of the reign of the same monarch.

BARRA, a district or kingdom on the banks of the Gambia in Africa, is said to be extremely populous, and chiefly inhabited by that race of negroes called Mandingos. Previously to the abolition of the slave-trade, this part of Africa supplied the West Indian colonies with great numbers of slaves. The Mahometan faith prevails; and a kind of monarchical form of government is established. But that a people in a great degree still in a savage state should be distinguished by so much prudence and moderation in their civil policy as has been described by travellers, must be ascribed to ignorance or credulity. The exaggerated statements alluded to represent the Mandingos as a wise, happy, and contented people.

The vegetable productions of warm climates are abundant; but it does not appear that much attention is bestowed on their cultivation. Salt is manufactured; the evaporation is conducted by the heat of the sun; and the produce forms a valuable commercial commodity, which is exchanged with the inhabitants of the inland parts of the country for maize, gold-dust, ivory, and cotton stuffs.

BARRA, or BARRAY, one of the Western islands of Scotland. See HEBRIDES.

BARREN ISLAND, an island in the Indian ocean, about 50 miles to the eastward of the Great Andaman, is 18 miles in circumference, and extremely conspicuous for a volcano which discharges enormous volumes of smoke, and great quantities of ignited matters, from a mountain which rises to the height of nearly 2000 feet above the level of the sea.

BARRINGTON, the Honourable DAINES, a naturalist and antiquary, was the son of Viscount Barrington. The father, who was raised to the Irish peerage in 1720, acquired some literary reputation as the author of *Miscellanea Sacra*, in which the means employed by the first preachers of the gospel in propagating Christianity are traced and examined, as well as of some other works. He was a warm friend and zealous advocate of the dissenters; and five of his sons were fortunate in attaining conspicuous stations in different departments of the state. Daines, the fourth son, was destined to the profession of the law; was appointed a Welsh Judge in 1757, and afterwards Justice of Chester, which latter he resigned in 1785, and retired to his chambers in the Inner Temple, where he died in 1800. His *Observations on the Statutes, chiefly the more ancient*, with a *Proposal for new-modelling them*, is reckoned a valuable treatise. But his *Experiments on the Singing of Birds*, and his *Essay on the Language of Birds*, published in "Miscellanies on various Subjects," in 1785, are considered the most curious and interesting of all his investigations, and are often alluded to by succeeding inquirers.

BARROLOOS, a tribe of people in southern Africa, who are said to inhabit a district ten days journey from Leetakoo, have numerous large towns, well built houses, and have made such progress in the arts as to extract iron and copper from their ores.

BARROW, Dr ISAAC, an eminent mathematician, and a learned divine, was born in London in 1630; and at Charterhouse, his first school, he gave no promise of future greatness; for an untoward temper, a slovenly habit, and obstinate idleness, were then his chief marks of distinction. But on his removal to Felsted in Essex, he was actuated by a better disposition; and the alacrity and success with which he now applied to study gave joy to his father, who, in his secret thoughts, had destined him to a learned profession; and his progress in learning was attested by his master, who appointed him classic tutor to Viscount Fairfax.

In 1645, he became a student of Trinity-college, Cambridge. Attachment to the royal cause had so ruined his father's fortune, that at college young Barrow found himself in a scene expensive beyond his means, and was glad to avail himself of the liberality of the celebrated Dr Hammond. In the course of his studies he perused the works of Bacon, Des Cartes, Galileo, and other eminent authors; and such was his reputation, that notwithstanding the unpopularity of his political opinions, he obtained a fellowship. With a view to the practice of medicine, he engaged with ardour in the study of anatomy, botany, and chemistry. But, through the advice of his uncle, bishop of St Asaph, seconded by his own views of the obligation of the oath which he had taken on becoming a fellow, he withdrew his attention from these studies, and directed it to others connected with mathematics. While he read Scaliger on Eusebius he saw that chronology depended on astronomy, and astronomy on geometry; and that his knowledge might rest on a sure foundation, he began the study of Euclid's elements, and persevered in the pursuit till he attained to eminence.

Having been disappointed in his expectation of succeeding Dr Dupart, as professor of Greek, he resolved to visit the continent. At Paris he found his father, who had followed the fortunes of the exiled Charles. From France he went to Italy, and spent some time in Florence, employed chiefly in the examination of books, manuscripts, and medals. The plague prevented him from visiting Rome. He spent a year in Greece and the adjacent countries; and read, while at Constantinople, the works of Chrysostom, whom of all the fathers he admired the most. He came home through Venice, Germany, and Holland, and hastened to enter into orders, expecting preferment on the restoration, of which, however, he was disappointed.

In 1662 he was nominated lecturer of geometry in Gresham college, London, and, not long after, declined a valuable living in the church, because it was encumbered with the education of the patron's son. In the following year he obtained, through the recommendation of Dr Wilkins, the mathematical lectureship which Mr Lucas had lately founded at Cambridge; and, to secure the object of the institution, he caused himself and his successors to be bound to leave annually ten written lectures to the university; and still more to illustrate this chair, he resigned it in favour of *Sir Isaac Newton*.

The study of theology and the composition of sermons now employed his time and exercised his talents; and in this, as in all his other pursuits, he soon rose into high excellence. In his 42d year he was made master of his college, on which the king declared that he had given a place to the best scholar in England. This was a station suited to Barrow's taste, and he sought for no higher promotion; but he did not on that account decline into idleness. He discharged the duties of his office with assiduity, added to the number of his sermons, and composed his treatise on the pope's supremacy. On the 4th of May 1677, a fever deprived the world of this ornament of mankind, who had taught them to explore the secrets of science, and to understand that wisdom that hath come from above.

As an author, Dr Barrow holds the highest rank, both in regard to the kind and the quality of his productions. He wrote poetry in Latin, on several subjects, but never indulged in satire,—"his wit was pure and peaceable." His principal works in mathematics are Euclid's Elements and Data; eighteen optical lectures, still held in high estimation; thirteen geometrical lectures, in which he treats of curve lines; some lectures composed while he was Lucasian professor. With the exception of two, his sermons are posthumous; but as he had transcribed them all several times, he left them prepared for the press. His style is nervous and bold; and his illustrations are often exuberant, combining his stores of erudition, his knowledge of scripture, and his experience of life. His language is sometimes older than his age, but it glows with the spirit of genius and piety. His admirable discourses, though long, are read without languor. He enlarges the understanding by the accuracy of his reasoning; he captivates the imagination by the splendour of his descriptions; he charms the heart by his display of the beauty of holiness. He was no less amiable as a man than great as an author. A culpable negligence of his person hurt him with those who only judge from outward appearance; but those who knew him best have borne ample testimony to his virtues; they pronounce him to be a man of strict integrity, warm benevolence, and pure piety, of great meekness of temper and gentleness of manners, an honour to his college, his country, and to human kind.

BARROWS, are artificial mounds of earth or stones, generally of a conical form, which seem to have been destined as repositories of the dead, or to commemorate some public event. They are common in many parts of the world. Such structures were well known to the ancient Greeks; and they are distinctly alluded to by Homer, as monuments reared as a tribute of regard and affection to the memory of their departed heroes. The barrow of Alyattes, father of Crœsus king of Lydia, is described by Herodotus as a vast mound of earth raised on a lofty basement of massy stones. This grand monument, which was three quarters of a mile in circumference, and 200 feet in height, was constructed by the united labour of the citizens. Similar structures of less magnitude, intended, it is conjectured, as the sepulchres of the younger branches of the royal family, are erected in its vicinity. The Grecian barrows were usually surmounted with the figures of animals, or with pillars containing inscriptions.

Monuments of this kind are not unfrequent in Britain. The urns, utensils, and warlike instruments found deposited in some of them, point out a Roman origin. But others are supposed to be the works of the Britons or Danes; and as they are more numerous in particular places, may it not be conjectured that such spots were regarded as the consecrated sepulchres of the dead, or the scene of some memorable battle. The barrows or cairns of Scotland include urns, containing burnt bones and ashes, or stone chests with the bones entire, or bones seemingly thrown together in a promiscuous manner.

Mounds of earth, or of loose stones, destined to a similar purpose, have been discovered in America, in some of which Mr Jefferson, who examined a number of them, found immense collections of human bones, which seem to have been deposited at different periods. Of the origin of the transatlantic barrows some diversity of opinion prevails. While they are supposed by some to have been the general sepulchres of great towns which once existed near the spot, others think that they are the tombs of the dead who fell in battle; and others have conjectured, that they are to be ascribed to the custom, which is said to be observed among the Indian tribes, of collecting, at certain periods, the bones of the dead into one great repository.

Mr Stackhouse, who has examined the ancient monuments of this description in the southern districts of Britain, advances another opinion of their origin and use; and supposes that they were intended for the purpose of direct and speedy communication of intelligence of the approach and movements of hostile invaders. In support of this opinion, he has traced these barrows through a considerable extent of country, and finds that they are so arranged and accommodated to the nature of the ground, and of such magnitude and height as the particular situation required, as admirably to afford the best means of uninter-

Barry. rupted communication. Gough's *Sepulchral Monuments of Great Britain*. Stackhouse's *Illustration of Ancient Barrows*. Jefferson's *Notes on Virginia*.

BARRY, JAMES, an eminent historical painter, and author, was born in Cork in 1741. His father a coasting trader, had destined him to his own perilous profession, and, with this view, he made several voyages across the British channel; but his aversion to a sailor's life was invincible; and instead of handling the ropes, and managing the sails, he was employed in sketching the coast, or drawing the figures which accident presented, or fancy chanced to suggest. Reluctantly allowed to follow the bent of his own inclination, he devoted himself entirely to the perusal of books, and the practice of drawing; and for these pursuits he abandoned all boyish amusements, neglected his sleep, and grew careless of his person. He read whatever books he could procure, took large extracts from some, and made complete copies of others: but he had most delight in drawing, in which he always aimed at a representation of action, attitude, and passion, choosing for this end historical subjects, such as Abraham's sacrifice, Daniel in the Lion's den, Susanna and the Elders, &c. At this youthful period of his life he is also said to have furnished a bookseller with drawings to decorate a volume of fables, published at Cork.

But he was soon to enter on an ampler scene. In the twenty-second year of his age he visited Dublin on the eve of an exhibition of paintings; into which he had the satisfaction to obtain admission for his picture of St Patrick baptizing the converted King of Cashel. The admiration inspired by this piece brought Barry into notice; and his own merit concurring with a letter of introduction from Dr Sleigh of Cork, procured him Mr Edmund Burke's valuable acquaintance, which a singular circumstance is said to have quickly matured into warm friendship and steady patronage. As they disputed concerning the arts, Barry strenuously defended the principles of a late anonymous publication; this book Burke at first treated as destitute of authority, and unworthy of attention; but seeing his antagonist's zeal rising into rage, he instantly appeased his passion by avowing himself its author. Barry now, in a transport of joy, inclosed Burke in his embrace, triumphantly displaying at the same time a copy of the essay on the sublime and beautiful, which, moved by admiration, he had entirely transcribed.

After a residence of some months in Dublin he accompanied Mr Burke's family to London, was introduced by his patron to the most eminent artists of that city; and was employed in copying, in oils, the splendid views of Athens by Stuart. Under the same auspices which brought him to London, he went, in 1765, to the continent, where he spent five years, mostly at Rome, devoted to the study of the numerous and excellent models of sculpture and painting treasured up in the Vatican, and the other collections of Italy. During this period, the intemperate language with which he maintained his very peculiar opinions involved him in unpleasant quarrels, and nourished in his ill-regulated mind a gloomy suspicion that haunted and tormented him to the day of his death.

He returned to England in 1771; and as, in one of his letters, Mr Burke had suggested, "that no man can draw perfectly who cannot draw beauty," he endeavoured to gratify his patron by a delineation of Venus, in which it is said he has succeeded in exhibiting grace and beauty in their highest ideal form. He applied to the practice of the art of historical painting with persevering diligence; and the productions of his pencil were numerous, and often excellent, at least in design. His pictures of Adam and Eve, to represent the ideal perfection of the human character—of Jupiter and Juno, to exhibit the sublime—of Mercury inventing the lyre, and Narcissus admiring his own shadow, to suggest the effects of industry and idleness—and of Job reproved by his friends, to disclose patience in affliction—are specimens of his skill which must be mentioned to his praise. But his obstinacy in refusing, on frivolous pretences, to listen to the solicitations of Mr Burke, reiterated for more than two years, urging him to paint his portrait for the use of their common friend Dr Brocklesby, alienated the affections of a man who had given him numerous and substantial proofs of his friendship. This involved him in the guilt of ingratitude; and although the portrait was at last finished, confidence and intimacy were for ever at an end.

In 1777, he began his great work at the Adelphi. The Society for the Encouragement of Arts, Manufactures, and Commerce, had accepted of his offer to paint their great room, had agreed to supply him with materials, and had allowed him the choice of his subject, which was a series of poetical and historical designs. The first is the story of Orpheus; the second a Grecian Harvest Home; the third the Victors at Olympia; the fourth the Triumphs of Navigation; the fifth the Distribution of the Society's Prizes; and the last is Elysium, or Final Retribution. He commenced this magnificent undertaking with only sixteen shillings in his pocket; and, during the seven years in which he was engaged with it, he procured a scanty subsistence by sketching designs, in the evening, for the printsellers. When he had completed his purpose, the Society expressed their approbation of this grand production of genius, patience, and self-denial, by allowing its author two exhibitions, which brought him about L.300, by voting him their gold medal and L.50 in money, and by granting him an additional L.200 afterwards.

Soon after his return from Rome, Barry had been elected an associate of the Royal Academy, and in 1782 he was appointed their professor of painting, with an annual salary of L.30. The manner in which he discharged the duties of this honourable office may be learned from a perusal of the lectures which he delivered to the associates and academicians. They are six in number,—on the history,—the design,—the composition,—the light and shade,—and the colouring of painting. Of these discourses, that of colouring is allowed to be the most perfect. During the period of his professorship, violent quarrels arose between him and his constituents. Induced by these dissensions, he published his letter to the Dilettanti society, in which he displays great enthusiasm for the arts, and great contempt of the royal academicians. On this letter, and on certain parts of his lectures they founded charges against him, accusing him of encouraging a disorderly spirit among the associates and students of the academy; in consequence of which he was, in April 1799, degraded from the professorship, and expelled from the academy.

These misfortunes came upon him in a train of other calamities: Old age was approaching; he was robbed of the money which would have alleviated its infirmities; his violent and suspicious temper deprived him of the confidence and the solace of friendship. In this forlorn condition he was indeed an object of compassion, and, through the benevolent exertions of several noblemen and gentlemen, L.1000 was raised by subscription, with which an annuity was bought from Sir Robert Peele. But Barry did not live to enjoy the benefit of this charity. He died of a pleuretic fever in February 1806. His body was laid in state in the great room at the Adelphi, surrounded by his own works; and, through the generosity of Sir Robert Peele, who contributed L. 200, his funeral was splendid.

All Barry's writings,—his correspondence,—his inquiry into the causes which have obstructed the progress of the arts in England,—his lectures,—his observations on the principal paintings in Italy, &c. &c. bear the marks of a vigorous mind and an original thinker. In his whole career he acted under the influence of a powerful enthusiasm, which made him attach an importance to his art that seems altogether extravagant. Having his mind thus bent to one object, he disregarded the regulations of civilized life, and retained, amid the most polished society, the habits of a savage. His temper was violent, and his language was rude. His house presented the picture of ruin,—destitute of comfort, cold, damp, and dirty. In religion he was a Roman catholic; and although for a while his mind hovered on the verge of infidelity, a perusal of Butler's Analogy established his faith, and henceforth he held it without wavering. His stature was below the middle size,—his figure broad and strong,—his features harsh, though abundantly expressive of intelligence. There was thus in his character much to praise, and much to blame, much that excites admiration, and much that fills us with disgust.

BARTHELEMY, John James, a celebrated French author, was a native of Cassis, a small seaport town of Provence, and was born in 1716. His early education commenced in the college of the Oratory of Marseilles; but as he was destined for the church, it became necessary to prosecute the study of philosophy and theology under the Jesuits; and by his ardent zeal and indefatigable industry, his progress in the knowledge of the Greek and Oriental languages was rapid and brilliant. But intense application greatly injured his health, and he had scarcely recovered, when he was admitted into the seminary where he received the tonsure. The reading of sermons in Arabic to an assembly of Maronites, Armenians, and other catholic Arabians, and his ability in conducting a learned dialogue with a Jewish Rabbin, who had embraced Christianity, are adduced as satisfactory proofs of his skill and proficiency in oriental learning.

Attached by inclination to literature, the young Abbé, with the view of confining his pursuits to a particular department of it as a profession, repaired to Paris in 1744; he had the good fortune to be recommended to the keeper of the royal cabinet of medals; and was no less fortunate in obtaining his friendship, in being appointed his associate, and finally in 1753 his successor. With all the ardour and industry which appeared so conspicuous in his former pursuits, he entered on this new department of study; and with the same assiduity he continued his labours through life in arranging this splendid collection, and in enriching it with many fine specimens furnished by an extensive correspondence in all parts of Europe. At the urgent request of the lady of M. de Stainville, better known afterwards as the Duke of Choiseul, the Abbé visited Rome while his patron was ambassador at the court of the Vatican. This visit afforded him a fine opportunity of gratifying his ardent curiosity in the study of classical antiquity. Proceeding to Naples, he contemplated with deep interest the rich treasures collected from the ruins of Herculaneum and Pompeii, and displayed in the museum of the palace of Portici; but he beheld with regret and surprise that the manuscripts lay in the same state in which they had been discovered; and no solicitations on his part, although urged with all the warmth of enthusiasm which such objects naturally excite in a profound classical scholar, made any impression on their possessors, either in directing their own ingenuity and industry in unrolling and reading these precious relics, or in permitting the labours of others to be bestowed on them. The keepers of the musuem were strictly enjoined neither to part with any of the manuscripts, nor to allow copies of any parts of them to be taken. Disappointed in his expectation of presenting his learned countrymen with a specimen of ancient Greek writing by direct application, the Abbé had recourse to what may be regarded as a pardonable artifice in the accomplishment of his object. He was permitted to examine, for a few minutes, a manuscript of 28 lines, and from recollection he made a *fac simile* of the whole, compared it with the original, corrected the errors, and transmitted it to the academy of Belles Lettres.

The advancement of the Duke of Choiseul to the head of the public administration was an event highly auspicious to the fortunes of Barthelemy. By the favour and influence of his patron, he was placed in various official situations which afforded him a liberal income, and a large portion of leisure for literary pursuits. In 1788 his greatest work, *The Travels of Anacharsis in Greece*, appeared, and had been the subject of occasional labour for 30 years of his life. Anacharsis, the hero of this narrative, a young Scythian descended from the famous philosopher of the same name, travels in Greece about the middle of the fourth century before the Christian era, and gives an account of the arts, institutions, and manners of the Greeks. This production, the fruit of extensive erudition, profound research, and unwearied industry, gave great celebrity to the author, acquired unusual popularity, and was translated into all the languages of Europe. In the succeeding year the learned author was admitted into the French academy.

The affluence and literary repose which Barthelemy had enjoyed during great part of a long life, were disturbed in the evening of his days by the storms of the French Revolution. The suppression of pensions and offices left him little more than the scanty means of subsistence; and the suspicion of aristocracy excited against him during the reign of terror, in 1793, endangered his life. He died in 1795, when he had nearly reached the venerable age of eighty.

BARTHOLINE, Thomas, a learned physician and anatomist, was born at Copenhagen in 1616, and having finished his elementary education in his native city, acquired his anatomical and medical knowledge in France, Italy, and Germany. Returning to Copenhagen, he was first appointed mathematical professor, and afterwards advanced to the anatomical chair; and was fortunate in the discovery of the lymphatic vessels while he was employed in the dissection of a live dog, and nearly about the same time with Olaus Rudbeck. He was the author of various works connected with the studies in which he was so assiduously engaged; and he was the editor of a treatise on anatomy by his father, who had been originally a medical practitioner and an anatomist, and professor of medicine in the university of Copenhagen, but having entered into the church, he was chosen professor of divinity in the same seminary. Thomas Bartholine died in 1680.

BARTHOLOMEW, one of the twelve apostles, is supposed to be the same with Nathaniel, one of the first disciples of Jesus Christ; according to Eusebius, he preached the gospel in India, returned to the more northern and western parts of Asia, and at last came to Armenia, where he suffered martyrdom.

BARTHOLOMEW, St., one of the Caribbee islands, in the West Indies, is about 24 miles in circumference, and is surrounded by a rocky coast, which renders access to it difficult. Cotton, lignum vitæ, drugs, and provisions, are the principal vegetable productions; but the soil is chiefly fitted for pasture land. The supply of fresh water is scanty, and mostly derived from the rain collected into reservoirs. St Bartholomew was originally settled by the French from St Kitts, in which neighbourhood it lies; and, after being in different hands, was ceded to the Swedes in 1785, and taken by the British in 1801.

BARTSIA, Painted Cup, a genus of plants belonging to the Didynamia class.

BARYTES, a peculiar earth, so called from its great specific gravity, and the discovery of which is to be ascribed to modern chemistry. It constitutes the base of *heavy spar*, a mineral which abounds in metallic veins. See Chemistry and Mineralogy.

BASALT, a mineral substance, which is very abundant in some parts of the globe, and is distributed in horizontal, inclined, or vertical strata, or exhibits a regular columnar form, of which the south-west side of Arthur's Seat, near Edinburgh, some of the western islands of Scotland, and especially Staffa, the north coast of Ireland, more particularly the magnificent colonnade at the Giants Causeway, the Faroe islands, Iceland, the Lipari islands, and the shores of Sicily, furnish excellent examples. See Mineralogy.

BASE, or Basis, a term of extensive application, signifying the lowest part of a thing, as, in *Geometry*, the base of a triangle is the lowest side; in *Architecture*, the base of a column is the pedestal, or lowest part of it; and, in *Chemistry*, it denotes the alkaline, earthy, or metallic constituent of a saline body; as when soda, lime, or lead is combined with sulphuric acid, forming Glauber's salt, or sulphate of soda, plaster of Paris, or sulphate of lime, and sulphate of lead.

BASELLA, Climbing Nightshade, a genus of plants belonging to the class Pentandria.

BASHAW, or Pasha, or Pacha, is the viceroy or governor of a city, district, or province, in the Turkish dominions. Two orders of bashaws are established. The highest order is designated bashaws with three tails, because they have three tails in their military standard. The authority of this order within their government is nearly equal to that of the Grand Signior himself. The executive and military power is united in their persons, and they exercise nearly uncontrolled authority over the property and lives of all those within their proper department. The power of bashaws with two tails is more limited. Life and death are not entirely at their absolute disposal; and when they are called into the field, they are under the command of the higher order of bashaws. Bashaw, without any specific appellation, is sometimes applied to the grand vizier, and by way of courtesy to those who hold conspicuous stations at the Ottoman court.

BASHEE, or Bashi islands, a group of islands between Formosa and the Philippine isles, in the Chinese sea, present a varied surface of rugged mountains and fertile vallies, and produce the fruits of tropical regions, with sugar canes and cotton.

BASHKIRS, a tribe of people subject to Russia, and inhabiting the banks of the Ural and Volga, are descended from the Nogay Tartars, resemble them in manners, and lead a pastoral life. They rear cattle, horses, and camels, cultivate a little barley and oats, and are successful in the management of bees. The Bashkir troops, of which they are required to furnish 3000 cavalry to the Russian army, are expert horsemen, and dexterous marksmen with the bow and arrow.

BASIL, Saint, who obtained the surname of the Great, was one of the most learned bishops of the early Christian church, was a native of Cæsarea in Cappadocia, studied at Constantinople and Athens, and having travelled in Syria, Egypt, and Lybia, devoted himself to a monastic life. He was admitted into the order of priesthood by the learned Eusebius, bishop of Cæsarea, and on the death of that patriarch he was recalled from religious retirement to be his successor. The controversy which then prevailed concerning Arianism, which he refused to embrace at the entreaty of the emperor Valens, had nearly involved him in persecution; and all his influence was fruitlessly exerted in composing the dissensions which distracted the eastern and western churches. He died in 379, and in the fifty-third year of his age. St Basil is regarded as one of the brightest ornaments of the early church. His powerful genius, his skill in controversy, and an exuberant flow of eloquence, placed him in the first rank in the age in which he lived. The Paris edition of his works, Greek and Latin, and in three vols. folio, is considered the best.

BASILISK, an imaginary animal of the reptile kind, to which very extraordinary powers were assigned in the descriptions of the older naturalists, among which, it was said, that its breath was so pestilential that no other animal could live near it, and even its look was fatal to those on whom it cast its eyes. But these idle stories, improbable in themselves, and fitted only to excite wonder, or to amuse credulity, are disproved by accurate observation, and sink into obscurity before the light of true knowledge.

BASINGSTOKE, a town of Hampshire in England, occupies a fine situation in a fertile open country, contains a population of 2589, and has some woollen manufactures, particularly shalloons and druggets. Its market for corn and malt is considerable, and is greatly facilitated by inland navigation. It is 46 miles west from London.

BASLE, Basil, or Bâle, a canton of Switzerland, stretching along the banks of the Rhine, about 20 miles in length, and at its greatest breadth about 16 miles, including an area of 160 square miles, and a population stated at 40,000, enjoys a fine climate, and from the diversified aspect of lofty mountains and fertile well cultivated vallies, presents some beautiful and picturesque scenery. The vallies afford abundant crops of grain, the hills are clothed with rich vineyards, the more elevated regions are adorned with waving forests, and the chain of Jura, rearing its lofty summits in the clouds, seems to form an insuperable barrier to the whole district. The woods abound with game, and the waters of the Rhine, as it rolls its noble current through the canton, are well stored with excellent fish.

The labours of agriculture are prosperous and productive. Silk stuffs, printed cottons, gloves, paper-making, bleaching, and dyeing, are the chief manufactures.

The administration of the affairs of the canton is entrusted to the *great* and *little* council. The great council is composed of 216 members; the little council consists of 60 members; and the four chiefs of the canton being added, make up the supreme council of 280 persons, in whom are vested the chief direction of affairs, legislative authority, and the disposal of the principal offices. But with all the boasted freedom and happiness which the civil polity of this canton was supposed to bestow, and with all the benefits attending popular elections, undue influence and intrigue crept in, and prevailed to such a degree as to induce the citizens of Basle to have recourse to the singular mode of choosing their magistrates, filling up vacancies in offices, and even supplying the vacant chairs in the university by lot. Basle was the first canton which separated from the ancient confederacy, and joined the French in their revolutionary career, and, according to the constitution established in 1801, formed a department.

BASLE, or Basil, the capital of the canton of the same name, occupies a fine situation on the banks of the Rhine, which, with its broad, deep, and rapid stream, separates the city into the large and small town, united by a magnificent bridge of 14 arches, and 600 feet in length, and is surrounded with walls and a ditch. The houses are remarkable for neatness and elegance; the streets and squares are spacious; and the public fountains, which are numerous, and copiously supplied with water from the neighbouring streams, are equally ornamental and salubrious. The cathedral, a grand Gothic edifice, which includes within its walls the tomb of Erasmus, the brilliant ornament of literature in the fifteenth century, cannot fail to be venerated by the classical scholar. The hanger, seal, some manuscript letters, and the last will of the same learned man, are still preserved with pious care in the public library, which is also enriched with other valuable manuscripts, and particularly with the letters of the early reformers; and in apartments connected with the same institution are deposited many original paintings of the celebrated Holbein, a native of the place. The university founded in 1460 has enjoyed great reputation, and has been adorned by some of the most illustrious names in science and literature.

Basle was at one time regarded as the most populous town in Switzerland. The population, it is stated, has been reduced to 14,000, owing, it is alledged, to emigration, a practice common throughout the Swiss cantons. The manufactures enumerated in the account of the canton, are chiefly confined to the towns. The invention of the manufacture of paper in 1417, and the discovery of the art of printing in the succeeding year, are claimed by the inhabitants. Basle is 120 miles north-east from Geneva, and 60 miles south from Strasburg.

BASLE, or Basil, a bishopric and province in the circle of the Upper Rhine in Germany, lies partly in Germany and partly in Switzerland, and is remarkable for its picturesque scenery. The bishop was a prince of the German empire before the annexation of the province to the French territory during the revolution, and has now probably been reinstated in his authority. The population is stated at 50,000, of whom 15,000 are protestants, who chiefly reside in the valley of Munster.

BASS, an island in the mouth of the frith of Forth in Scotland, is about three miles distant from the southern shore, scarcely exceeds half a mile in circumference, and, excepting on the south-west side, where landing is not without difficulty, rises precipitously from the ocean not less than 400 feet above its surface. The rocks are chiefly of a basaltic nature; they are adorned with the sea tree mallow, *lavatera arborea*, one of the most splendid native plants, which grows to the height of six feet; some scanty herbage affords pasture to a few sheep; and the Bass has been long famous as the summer resort of the solan goose, one thousand of the young of which are annually caught for the Edinburgh market. These birds usually appear about March and April, and migrate in September.

The Bass, which is now part of the North-Berwick estate, was once public property; and during the distracted reigns of Charles II. and his successor, served the purpose of a state-prison. At the revolution it was held by some of the adherents of James, and is said to have been the last place which yielded to the new government. The fortifications were then dismantled.

BASS-STRAITS, the channel which separates New Holland from Van Diemen's land, derives its name from Mr Bass, a surgeon of the British navy, the enterprising discoverer, who explored it in an open boat through its whole extent. The voyages of future navigators have confirmed his discovery, and have contributed additional information to render its geographical details more complete and satisfactory. The channel is reckoned to be about 50 leagues from east to west, and the breadth in many places from north to south is not less. The passage through this channel, although somewhat dangerous from numerous rocks and islands, abridges the voyage from Europe to India, and the seal-fishery on the shores and islands promises to become a lucrative branch of commerce; but the number of adventurers, among whom the Americans were active and industrious, soon greatly exceeded the prolific supply of the animals, the fishery declined, and the British settlement at Fort Philip, on the northern shore, has been abandoned. Collins's *Account of Botany Bay*.

BASSANO, a town on the river Brenta, in the Trevisano in Italy, contains a population exceeding 11,000, with 30 churches and two monasteries. The manufactories of silk and woollen are considerable, and the business of printing is extensively conducted. A severe action between the French and Austrians was fought near Bassano, in the early period of the French revolution. Bassano is 12 miles north from Vicenza.

BASSET, a game which is played with cards, and is of so hazardous a nature, that it is said the inventor, a noble Venetian, was banished; and very severe edicts were made against it by Louis XIV. after its introduction into France.

BASSET, or BASSETING, terms employed in coal-mining operations in some districts, and are analogous to the *crop* and *cropping* out of the coal stratum, or that part of the inclined stratum which comes nearest to the surface of the earth.

BASSO RELIEVO, or LOW RELIEF, is that kind of sculpture in which figures are so represented that no part is detached from the back ground, and is distinguished from *alto relievo*, *high* or *bold relief*, in which parts of the figures rise above the surface.

BASSORA, or BUSSORA, a commercial city of Arabia Irak, occupies a central position between the junction of the Tigris and Euphrates and the Persian gulf, dates its origin from the caliph Omar, about the 16th year of the Hegira, who planned and built it for the purpose of facilitating the trade between the eastern empire and India, and continued under the Saracens till the Turks became its masters, about the middle of the 17th century. It afterwards fell into the hands of the Persians, but after a short possession was evacuated, and has since been subject to the dominion of the Ottoman Porte. In modern times, Bassorah has sustained numerous unsuccessful attacks from the new sect of the Wachabees.

The population of Bassorah, composed of Christians, Jews, Persians, Indians, and Arabians, is stated at 40,000, probably from its languishing commerce, a much smaller number than it could boast of in the days of its prosperity. But it is still a considerable emporium for exchanging the merchandize and manufactures of the west for the rich productions of eastern regions. The annual amount of the trade of Bassorah, was some years ago, according to Abbé Raynal, equal to L.525,000 Sterling. It is now chiefly in the hands of the English and Arabians.

BASTIA, a sea-port town, and capital of the island of Corsica in the Mediterranean, contains 6000 inhabitants, and has been often the object of attack and defence during the political struggles which have disturbed the repose of Europe. It fell into the hands of the British in 1794, but has been, since the general pacification, restored with the island to its former masters. The harbour is sufficiently commodious for small vessels, but the trade is not considerable.

BASTILE, the well known and once dreaded state prison of France, stood near the gate of Paris, on the road which leads to St Anthony, and was erected in 1370, in the reign of Charles V. by D'Aubriot, mayor of Paris, who it is said became its first inhabitant. The word signifies a *building*, and similar structures, destined to similar purposes, were established in different parts of the French dominions. The original building consisted only of two towers, on opposite sides of the street, and connected by a wall, in the centre of which was the opening for the city gate. This gate was closed up when a new approach to that quarter of the city was made; other towers were raised, and with connecting walls formed two complete courts; and the whole was surrounded by a ditch secured by a counterscarp. The walls of these courts were of immense thickness, and the height from the pavement in the inside was not less than 80 feet. Succeeding monarchs extended and strengthened the various parts of this immense fabric, as jealousy or despotism required. The towers, the usual places of confinement for those who were unfortunately immured in the Bastile, consisted of a sunk story, or dungeon, and four upper stories. The dungeon was paved and arched with stone; a little light was sometimes admitted, and sometimes it was entirely excluded; but no stove or fire-place was ever allowed. The dungeons of the towers, it is said, were assigned to those who had attempted to escape. The four stories of the towers formed each a single apartment of 18 feet diameter, and of the same height. The walls of the upper stories were 12 feet thick, and those of the lower apartments were still thicker. A single window admitted light to each apartment; the windows and chimney were secured by strong double gratings of iron, and the double doors were of oak-plank, and each three inches thick. A bed, a table, a chair, and a few necessary utensils, constituted the whole furniture. The whole internal management of the Bastile was entrusted to a governor and his inferior officers. Physicians, chaplains, and a company of invalids composing the garrison, were also attached to the establishment.

Those who became the objects of royal or ministerial resentment, were committed to the Bastile by secret orders, called *lettres de cachet*, in which no specific charge was brought against them, no period fixed for bringing them to trial; and thus all hope of regaining their liberty vanished. They were precluded from all connexion with their friends or the world. Insidious questions were proposed to them during their examination, and the hesitating answers were recollected and recorded, and thus they were often brought to involve themselves in imaginary guilt. It is said that torture was at one time employed to extort information, and that poison had been secretly administered to remove those whose presence had become too obnoxious even within the walls of these dreary mansions. But the uncertain state of mind, under which some of the inhabitants of the Bastile passed the tedious days of their imprisonment, was the bitterest cup of their misery. Often altogether ignorant of the cause of their confinement they saw no prospect of its termination. The history of the Bastile, accordingly, furnishes some examples of periods of imprisonment which seem almost incredible. When Louis XVI. ascended the throne, he ordered the registers of the Bastile to be examined, and some of the prisoners to be released from confinement. Among the number was an old man, who had been secluded from the world for the long space of 47 years. When his liberty was announced to him, he seemed scarcely to understand its meaning, and received the news with none of those feelings of lively joy which the prospect of so great a boon usually inspires. Leaving his dungeon, and being conducted to the street where he had once lived, he could not discover the least trace of his former abode; a public building was erected on the spot where it had stood. His family and relatives were all dead or dispersed. None of those, even the most advanced in life, whom he addressed, remembered him, or recollected any of the events to which he alluded. A whole generation had passed away; a new race had sprung up; and in his native city he was an utter stranger. From an old domestic, whom he accidentally discovered, he learned that his wife, worn out with anxious expectation and unavailing sorrow, had sunk to the grave 30 years before; and that his children had gone abroad to distant climes. At this tale of woe, the aged man, seeing himself left alone in the world, groaned deeply, and, it is said, actually applied to the minister to be restored to his prison, adding, " Is it possible in the same moment to hear of this universal destruction and not wish for death? How can I survive the loss of relations, of friends, of a whole generation. There seems nothing terrible in dying; but it is indeed a dreadful thing to be the last." The minister had compassion on the unfortunate old man, caused the ancient domestic to attend him, for he only could converse about his family; and this was the single consolation which he enjoyed in the new scene of his existence, which the chagrin and mortification of being the last of his race soon closed.

The Bastile became an object of the fury of the populace at an early period of the French revolution. On the 14th of July 1789, it was attacked and taken by the Parisian mob, and afterwards razed to the ground. Seven prisoners only were discovered within its walls, and none of them appeared to have been the victims of tyranny or wanton oppression. Six of that number were Frenchmen, one of whom was deranged; four were imprisoned for forgery; and the fifth, who was of the rank of nobility, had been arrested and confined at his father's request. The seventh prisoner was an Englishman, also in a state of mental derangement.

BASTINADO, or BASTINADE, a mode of punishing offenders which was practised among the nations of antiquity, and is common in eastern countries at this day. The name is derived from the French *baston*, signifying a *stick* or *staff*, the instrument of punishment. *Fustigation*, or beating with sticks, was well known to the Romans; and the bastinado of modern times is a summary mode of punishment among the Turks and Chinese. The offender is laid prostrate on the ground, his legs are raised and secured by the ancles in a wooden apparatus, and two men, each with a rod about the thickness of a small walking staff, beat alternately on the soles of his feet till the number of strokes, from a few dozens to 300 or 400, according to the sentence, be completed. A fine, the amount of which is regulated by the number of strokes inflicted, also accompanies this punishment among the Turks.

It is not a little singular that this mode of punishment should not be regarded with ignominy among their Chinese,—a remarkable feature in the character, when contrasted with the manners and feelings of Europeans. The emperor himself orders this chastisement to be inflicted on his courtiers, who are not disgraced, but consider it as a mark of paternal care, receive it with gratitude, are again admitted into favour, and treated with peculiar respect. Every mandarin has the power of ordering a similar punishment to be inflicted on petty offenders. In the hall of judgment a bag filled with small sticks is placed on a table before him. The signal of punishment is to take one of the sticks from the bag, and to throw it on the floor towards the offender, who is immediately seized by the attendant officers, thrown prostrate on the ground, and receives five smart blows from one of the officers, and the same number from another; and if the mandarin take another stick from the bag, the same process is repeated, if not, the punishment is completed, when the culprit falls on his knees before his judge, and with three inclinations of the body, thanks him for the paternal concern which he has thus expressed for his morals.

BASTION, a term in fortification, signifying a mass of earth faced with sods, brick, or stone, and projecting from a rampart. Bastions are said to be *solid* when the interior is entirely filled up,—*void*, or *hollow*, when the inside is empty. A *flat* bastion is built in the middle of the curtain, when it is too long to be defended by the bastion at its extreme parts. A *cut* bastion has the point cut off, and instead of it a re-entering angle, with two points outwards. A *demi* bastion is composed of one face, and has but one flank. A double bastion is raised on the plane of another bastion.

BAT, a genus of animals belonging to the class Mammalia. See *Vespertilio*, under MAMMALIA.

BATALHA, a small village about 60 miles north from Lisbon in Portugal, which is remarkable for one of the most magnificent specimens of Gothic architecture in Europe. This splendid structure is indebted for its origin to Don John, the first of the name as king of Portugal, who being invaded by the king of Castile with a powerful army, invoked the protection of the Virgin, and having defeated his enemy, raised this noble structure as a lasting memorial of his gratitude. The monastery of Batalha was founded in 1385, and the architect who designed and constructed this grand edifice was, it is said, a native of Ireland. The whole building, but especially the mausoleum of the founder himself, is richly decorated with an immense profusion of all kinds of ornaments, some of which are of a hieroglyphical description, and are scarcely intelligible. The monastery of Batalha is the burying-place of the royal family of Portugal. The earthquake of the first of November 1755, which laid Lisbon in ruins, and was felt throughout Europe, did considerable injury to the buildings; and the spire of the mausoleum was thrown down. The curiosity of those who wish to be acquainted with this magnificent Gothic structure, will be amply rewarded by consulting the splendid work of Mr Murphy, exhibiting *plans, elevations, sections and views of the Church of Batalha.*

BATAVIA, one of the principal towns of the island of Java, and formerly the capital of the Dutch settlements in the East Indies. See JAVA.

BATCHISARAI, or BAKTCHISARAI, a town of the Crimea, which is famous as the ancient residence of the Tartar khans, or governors of the country, and occupies the sides of two mountains and the intermediate valley which is traversed by a river. The streets are long and narrow, and are filled with shops. But the towers of numerous mosques, the tall poplars, the terraces, fountains, and hanging-gardens, render the whole scene extremely picturesque, when it is seen from a distance. The population, composed of Tartars, Jews, Greeks, and Armenians, is nearly 6000; and cutlery, morocco leather, woollen stuffs, and rope-making, are the chief manufactures.

BATH, a city of Somersetshire in England, is finely situated on the side of a narrow valley on the banks of the Avon, is well sheltered by a range of hills on all sides, excepting to the north-west, where the vale expands into rich meadows, and derives its modern, as well as its ancient names, from the quality or uses of its copious mineral springs. The "hot waters" of Ptolemy; the AQUÆ SOLIS, "waters of the sun," of the Romans; "the city of baths" of the Britons, and the "city of valetudinarians" of the Saxons, have each its obvious allusion.

Ancient city.—The local position of Bath, and the enjoyment of warm-bathing, so congenial to the habits of the luxurious Romans, rendered it a favourite residence, and one of their chief towns during their stay in Britain. Two spacious streets, crossing each other at right angles, and terminating in four gates, which looked to the four cardinal points, divided the town into four parts, and gave it a regular form. The general outline was somewhat of a five-sided figure, the sides of which were nearly equal; and a wall composed of stone and brick, 20 feet in height, and flanked with round towers at each angle, included an area of 1000 square yards. The temples, baths, and other public edifices which they erected, were of the most magnificent description. In 1755, the remains of an elegant structure, destined to the purpose of a sudatory, was discovered 20 feet below the surface, in digging the foundation of a modern building. The floor of the ancient fabric, which was still entire, was supported by pillars, and surrounded by tubulated bricks, to permit the passage of the heat and vapour. This bath was supplied from a hot spring; and the sewer for the conveyance of the waste water was still in a perfect state. But the repossession of Bath by the Britons after the departure of the Romans, or the succeeding invasion of the kingdom by the Saxons, was fatal to the splendour of this fine city. A period of 200 years had scarcely elapsed, when the Roman city had totally changed its aspect; and Roman magnificence could only be traced in the fragments of columns, sculptures, and other architectural decorations inserted into the walls which the invaders had erected for their own defence. Amidst the revolutions of the kingdom, and the various changes of its own fortunes, Bath seems to have been always a place of importance and consideration. The population was respectable at the time of the Norman conquest; in the time of Henry VIII. the manufacture of woollen stuffs was prosperous; and for the improvement of its municipal institutions, Queen Elizabeth renewed and enlarged its charters and privileges.

Modern city.—Bath, in its present state, is pronounced the pride of England and the admiration of foreigners; and its elegant streets, spacious squares, and magnificent buildings, seem to entitle it to this distinguished appellation. The Royal Crescent, a noble assemblage of thirty houses, distributed in an elliptical form, and adorned with Ionic columns, supporting the superior cornice, commands a picturesque view of great part of the city; the Circus, in which the buildings, decorated with three ranges of pillars of the Doric, Ionic, and Corinthian orders, are disposed circularly, and constructed according to the same uniform design, has, in the centre, a fine reservoir of water, collected from springs in the higher grounds, and destined to supply the neighbouring streets; and the Old Assembly Rooms, 90 feet in length, 36 feet in breadth, and 34 feet in height, afford a charming prospect of the river and the surrounding hills; but the New Assembly Rooms, completed in 1771, are still more spacious and elegant; of which the ball-room is 106 feet long, 42 feet wide, and the same dimensions in height; and of two card-rooms, one is of an octagonal form, and 48 feet in diameter, and the other, of a rectangular form, is 70 feet long and 27 feet broad. The public hospitals, for the relief of the sick and poor, are numerous and well-regulated, and some of the edifices are elegant structures. The Abbey-church, with its noble tower, rich west window, and arched door-way, and the splendid monuments with which the inside is decorated, is an admired specimen of architecture.

Waters, baths.—The Bath water is impregnated with a small portion of iron, a little calcareous and siliceous earth, and a small proportion of azotic and carbonic acid gases. Beside a number of private baths, four on a large scale, destined to the use of the public, have been constructed. The King's bath, 68 feet long and 40 broad, is supplied from a spring in the centre, which is inclosed by a brass rail, and is surrounded by an elegant Doric colonnade; the Queen's bath, supplied from the former, is a bason 25 feet square; the Cross-bath, at the end of Bath street, is of a triangular form; and the hot-bath, in which the water rises to the temperature of 117° Fahrenheit, is erected at the distance of 120 feet from the King's bath.

Population, &c.—The number of inhabitants estimated at 27,686 in the year 1801, had increased in 1811 to 31,496. Bath may be regarded as a place in which, from the great resort of fashionable company, the wealth and taste of the kingdom are displayed, rather than the seat of trade and manufactures. The amusements are regulated and conducted according to the most polished forms of etiquette; the rides and walks in the vicinity are delightful; and accommodations of all kinds for those who seek health or pursue pleasure, are abundantly provided.

Bath has been long distinguished by a respectable institution, the Bath and West of England Society for the Encouragement of Agriculture, Manufactures, &c. and the intelligence and activity of its members are sufficiently conspicuous in the volumes of its Transactions before the public. The Philosophical Society, for the purpose of promoting literature and science, was instituted in 1799. Bath and Wells form one bishopric, and the diocese includes the whole of Somersetshire, excepting a few churches in the city of Bristol. Warner's *history of Bath*.

BATH, Knights of, a military order in England, which is supposed to derive its name from the ancient practice of bathing, which was one of the solemn *rites* observed previously to installation, and an emblematical expression of the obligation to preserve integrity and purity of mind. It is supposed that this order was introduced into England by the Saxons; William the Conqueror conferred it both on his Norman and English subjects; but it seems not to have been fully instituted till the time of Henry IV. who, on the day of his coronation, nominated forty-six companions. It continued afterwards, at the celebration of the royal nuptials, or other solemn occasions, to be the practice of his successors to create Knights of the Bath; and at the coronation of Charles II. a splendid installation of sixty-eight knights took place. It fell into disuse till the year 1725, when it was revived by George I. erected into a military order, to be composed of a grand master and thirty-six knights-companions, and regulated by a system of statutes drawn up for its government. See Heraldry.

BATHING is the immersion of part or the whole of the body in water or some other fluid. Cold and hot water, salt and fresh water, mineral waters, and steam or vapour, are employed with different intentions for the purpose of bathing. See Materia Medica.

BATNIR, the capital of a district in the north-east quarter of Hindostan, some parts of the district of which are near the banks of the rivers, and have the advantage of annual inundations, are distinguished by the fertility of the soil, and produce abundant crops of rice, wheat, and barley; but the more elevated regions, which are subject to severe droughts, are no less remarkable for their sterility.

The inhabitants of this country, who profess Mahometanism, are described as a cruel and ferocious people, addicted to plunder from their earliest years, and even, it is said, wantonly putting to death the unfortunate victims who fall into their hands.

BATRACHOMYOMACHIA, from the Greek, signifying the Battle of the Frogs and Mice, is the title of a burlesque Greek poem, which has been generally ascribed to Homer. The subject of the work is the death of a mouse, who being mounted on the back of a frog, on a voyage to her palace, to which he had been invited, was seized with fear in the middle of the water, fell off, and was drowned. The mice, suspecting that their friend had not been fairly treated, demanded satisfaction, and declared war against the frogs.

BATTALION, a body of infantry composed of an indeterminate number of men, varying from 500 to 1000. In the British army, some regiments consist of a single battalion, but others have two or more.

BATTEL, or Battle, a town of Sussex in England, which is famous in history on account of the abbey called Battel abbey, which was erected by William the Conqueror to commemorate his victory over Harold king of England on the 14th October 1066. The magnificent remains of this edifice, which are yet visible, afford ample proof of its ancient splendour. Battle has been long celebrated for the manufacture of gunpowder of an excellent quality; the number of inhabitants in 1801 exceeded 2000, and the distance from Hastings is six miles, and from London 57 miles.

BATTEL, or Battle, or *Trial by Wager of Battle*, is a mode of deciding differences which was resorted to in the less civilized periods of society in Europe, and no doubt derived its origin from the military spirit of the times, and the pious but superstitious confidence in the interposition of heaven in favour of the injured party. The regular forms of judiciary combats are supposed to have been first introduced among the Burgundi, a tribe of Germans who settled in Gaul. But a wider range of observation may trace the spirit of the practice, if not the formal solemnities, to every ancient warlike nation. Under the immediate influence of their tutelary divinities, the heroes of Homer often engaged their enemies in single combat; aided by the God of battles, David, on the part of Israel, slew Goliah, the champion of the Philistines; and of a similar character, although three warriors fought on each side, was the desperate conflict between the Horatii and Curiatii, which holds so conspicuous a place in Roman history.

But the judiciary combat assumed its most prominent feature in the feudal ages, and became a part of the civil polity of those countries where feudal institutions were established. This mode of trial was introduced into England by William the Conqueror, and it was employed in military, criminal, and civil cases; the first in the court martial, or the court of chivalry and honour, the second in appeals of felony, and the third upon issue joined in a writ of right, the last and most solemn decision of real property. The last trial of this kind, waged in the Court of Common Pleas at Westminster, was in 1571, in the time of Queen Elizabeth, and was held in Tothil-fields. In 1631, a trial by battle took place in the court of chivalry; and a similar case occurred in 1638, in the county palatine of Durham. Of the equity of such decisions, no remark is necessary to rational readers; and yet the duel of modern times, which is still resorted to as the test of honour, and practised in open violation of the laws of God and man, may justly be regarded as a barbarous remnant of the false notions in which the whole system originated.

BATTERING, in modern warfare, is the attack of a strong place with heavy artillery.

BATTERING-RAM, an ancient military engine, which was employed in beating down the walls of besieged places, which is said to have been invented in the fifth century before the Christian era. This machine was composed of a beam, sometimes 80 and 100 feet in length, headed with iron resembling a ram's head, from whence the name, and suspended by ropes from a strong frame, which moved on wheels. The iron head of the beam was propelled against the wall intended to be battered, by the labour of men; and sometimes not fewer than a hundred were employed in the operation.

BATTERY. See *Fortification* under WAR.

BATTERY, Electrical and Galvanic. See ELECTRICITY.

BATTLE, an engagement between two hostile armies. See WAR.

BAVARIA, a circle or kingdom of Germany, situated between 47° and 48° of north latitude, and 10° and 13° of longitude east from Greenwich; is bounded by Franconia and Bohemia on the north, by Austria and Styria on the east, by Carinthia and Tyrol on the south, and by Swabia on the west, and contains the archbishopric of Salzburg, indenting itself between Austria and the Tyrol, the duchy of Bavaria occupying the south-western division, and the palatinate reaching from the Danube to the confines of Franconia and Bohemia. This region from south to north extends 200 British miles in length; and from east to west it is about 130 in breadth.

Physical state.—The external appearance of Bavaria is greatly diversified by high mountains and deep vallies; by numerous lakes, and copious streams; by large cities, and smaller towns; by stately mansions, and scattered hamlets. Many of its mountains, especially toward Tyrol, rise to the clouds in bold, precipitous, rocky masses; many of them are thickly clothed with deep, and even impenetrable forests; and many of them are verdant with rich and luxuriant pastures. They are composed of granite, gneis, micaceous, and argillaceous schistus; and in many places abound with metallic ores. A multitude of lakes, to the number of 176, as travellers report, of various sizes, and at frequent intervals, is scattered over the whole of the southern side of the country; and these lakes, which derive their waters from the melted snow of the mountains, feed the rivers which traverse, beautify, and enrich the region. Of these rivers the majestic Danube, in its course from Swabia towards Austria, divides Bavaria into two great departments, and is augmented by numerous tributary streams. Except the Altmuhl and the Nab, the rivers of the division north of the Danube are not considerable; but that of the south, which is the region of the lakes, is intersected in every direction by many large streams. On the east, the Inn, which rises in Switzerland, and flows towards the Danube, through the archbishopric of Salzburg, forms the line of separation between Austria and Bavaria; and the Lech, which has its source in Tyrol, divides it from Swabia; and the Iser, as it winds its way in the same direction through the heart of the country, receives many tributary streams.

Productions.—Bavaria is rich in minerals; in her rocks are mines of gold, silver, copper, iron, and lead; also quarries of marble, with an endless store of architectural materials. Pearls have been found in some of her rivers; and her alum and salt excite the industry of the people, and afford a revenue to the state. Her mountainous soil, indeed, is less adapted for the culture of corn than for the rearing of cattle; but on the banks of the rivers. and in the retired vallies, are many fertile tracts; and most of that part of the country which stretches from Munich to the Danube, is well fitted for all the purposes of agriculture. But this art, which tends so much to promote the beauty of a country, and to secure the independence, and mark the improvement of a people, has hitherto, in Bavaria, continued in the most wretched condition. Under a proper system of management she might easily support a far denser population, well supplied with the richest gifts of the teeming earth; her warm vallies would nourish the vine, and bring to maturity some of the choicest fruits,—would crown her year with abundance, fill her barns with plenty, and the houses and the hearts of her inhabitants with gladness. And yet, through neglect, induced by ignorance and impolicy, this country, so highly favoured by nature, continues almost destitute, not only of orchards and vineyards, but even of the common culinary vegetables, and knows no other system of culture but that which has descended from remote and barbarous antiquity.

Social and political state.—The population of Bavaria has lately been ascertained with all the inquisitorial scrutiny which marked the reign of Napoleon Bonaparte. By his ordonnance, issued in the year 1808, it was divided into the following 15 circles: Mein, Pegniz, Nab, Retzal, Altmuhl, Upper Danube, Lech, Regen, Lower Danube, Iser, Salzbach, Iller, Inn, Eisak, and Adige, extending over a surface of 1636 square miles, and containing 3,231,538 inhabitants.

Cities.—Bavaria is thickly studded with cities, towns, and villages, of which the principal are Munich, the capital of the country, built on the Iser, adorned with an elegant palace, and many other public buildings, and enriched also by an academy of sciences founded in 1759, and inhabited by more than 50,000 human beings: Ingolstadt, 45 miles north of Munich, the seat of a university; this town contains 7000 inhabitants, is regularly built on the Danube, it is fortified by a wall and environed by a marsh, so that it is one of the strongest towns in Germany: Friedberg, a little town, but famous for clocks and watches: Salzburg, the capital of the archbishopric of that name, situated amid wooded rocks and cultivated hills, having a university, a cathedral, a palace, and 15,000 inhabitants: Amberg, the capital of the palatinate, a fortified town, with a palace, a cathedral, &c. and about 5000 inhabitants: Passau, built on a hill at the conflux of the Inn and the Danube, a trading town, with 9000 inhabitants, famous for the treaty between Charles V. and the Elector of Saxony, concluded in 1552; and Ratisbon, an imperial city, at the conflux of the Regen and the Danube, fortified in the form of a crescent, and containing nearly 30,000 inhabitants.

Manufactures, &c.—Those arts which minister to the luxury of the opulent, are more practised in Bavaria than such as tend to excite the industry and enterprise of the people; to open the sources of individual emolument and of national wealth, and to promote the solid enjoyment and the respectability of life. She has in her capital more goldsmiths and engravers, hairdressers and gingerbread-bakers, than manufacturers of leather, or woollen, or cotton-cloth. Tobacco and salt are the staple commodities which are prepared for the market, as well as produced in the country. But she exports great quantities of timber, iron, rough hides, raw wool, &c.

Government.—The assembly of the states of Bavaria is made up of three orders,—the prelates, the nobility, and the people. The half of the votes belong to the nobility, and the other half is divided equally between the other two orders. The duchy is divided into four governments,—Munich, Straubing, Landshut, and Burghausen, each of which is represented by two peers, a prelate, and a deputy for the towns, in the assembly of the states. The hereditary offices of the elector, now the king, are the governor of the royal domains, the steward, marshal, cup-bearer, and huntsman. In respect of rights and dignities, the king, except the circumstance of his new title, is nearly on the same footing with the electors before him. He is arch-seneschal of the empire.

Revenue.—A tax is levied on all the land of the electorate without exception. The 25th part of the produce constitutes the tax, for which the farmer has a draw-back for feu-duty and the expense of culture. This impost on the land is denominated the general revenue of the country. The electoral revenues arise from fines, quit-rents, escheats, and other baronial rights, from duties on breweries, on the commodities consumed in the towns, on salt-works, coinage, the produce of the forests, and on imports; the annual amount of the whole of these imposts is estimated at 12,000,000 of florins. Bavaria maintains a military force of about 12,000 men. They are said to be impatient of discipline and order, much disposed to ravage a hostile country, but withal exhibiting occasionally surprising feats of bravery.

Religious and moral state.—The Roman catholic religion is established in this part of Germany. The archiepiscopal see of Salzburg was founded by Rupert, an Englishman, in 716. The archbishop is primate of all Germany, and as, of the 24 persons of high rank which compose his chapter, 20 are Austrians, the whole court, in political matters, is under the influence of Austria. The whole country abounds with religious houses, churches, chapels, and convents; and swarms with ecclesiastical persons of different orders, full of mutual hatred towards each other, but maintaining an unlimited influence over the people of every rank. Half of the inhabitants were once protestants, but, owing to the persecutions by which they were harassed, most of them have abandoned their native soil for the woods of America. Indulgences are sold at a moderate price for the most enormous crimes. After this it will be unnecessary to add, that superstition and bigotry are the prominent qualities of a Bavarian's religious character. It is easy to infer the moral influence of such a corrupted creed; and in this the most uncharitable reasoner will not exceed the truth. The representations which travellers have given us of the disgusting grossness of the Bavarian manners, seems indeed almost incredible. The peasants are coarse, slovenly, and ferocious, living in hovels full of smoke, filth, and vermin. The court of Munich maintains no less than four thousand men, who, from ignorance, have no relish for rational employment, but spend their whole time in gaming and debauchery. Their example is imitated, and the contagion spreads throughout the country, till, according to the remark of a Gascon officer, Bavaria has become the largest brothel in the world.

Characteristic incident.—A scene, of which Baron Reisbach was an eye witness, will illustrate Bavarian superstitiou and brutality. "I happened, says the Baron, to stroll into a dark black country beer-house, filled with clouds of tobacco, and on entering I was almost stunned with the noise of the drinkers. By degrees, however, my eyes penetrated through the thick vapours, when I discovered the priest of the place among fifteen or twenty drunken fellows. His black coat was as bad as the frocks of his flock, and, like the rest of them, he had cards in his left hand, which he struck so forcibly on the dirty table, that the whole chamber trembled. At first I was shocked at the violent abuse they gave each other, and thought they had been quarrelling, but soon found that the appellations which shocked me were only modes of friendly salutation among them. Every one had drunk his six or eight pots of beer, and they desired the landlord to give them a dram of brandy, by way they said of locking the stomach. But now their good humour departed, and preparations were made for a fray, which at length broke out. At first the priest took pains to suppress it; he swore, he roared as much as the rest. Now one seized a pot and threw it at his adversary's head; another clenched his fist; a third pulled the legs from a stool to knock his enemy on the head; every thing seemed to threaten blood and death, when, on the ringing of a bell for evening prayer, *Ave Maria ye!* cries the priest, and down dropped their arms, they pulled off their bonnets, folded their hands, and repeated their Ave Marias. As soon, however, as their prayers were over, their former fury returned with renewed violence; pots and glasses began to fly. I observed the priest creep under the table for security, and I withdrew into the landlord's bed-chamber."

After this, we are not surprised to learn from the same author, that in external appearance a Bavarian is a most grotesque figure, rather a caricature than a man. His head is round, and his chin peaked; his belly is prominent, and his legs short and unshapely, his eyes sunk, and his complexion pale; the whole exhibiting the most ungainly awkwardness, and betraying inbred depravity. But how is this description to be reconciled with that of the women, with which it is completely contrasted? They are represented as being exquisitely beautiful. Their form is perfect symmetry,—the pure whiteness of the lily, softly tinged with warm purple, as if by the hands of the graces, gives a clear transparency to their complexions; their manners are lively, graceful, and elegant; in short, from head to foot, in body and mind, they are said to be altogether lovely.

History.—Bavaria derives its name from the Boii, an ancient Celtic tribe of Gaul. During the decline of the Roman empire, and the kingdoms which rose on its ruins, she was subject to many masters, and was severed and separated into many fractional parts, according as the sons and servants of her conquerors were in want of inheritances. In the ninth century the Francic family assumed the title of kings of Bavaria. In the thirteenth century the house of Bavaria acquired the palatinate by marriage. Frederick V. elector palatine, married the daughter of James I. of England, and aspired unsuccessfully to the crown of Bohemia. But, by the treaty of Westphalia, his son regained the dominions which had formerly belonged to his family, and was created eight elector of the empire. Maximilian II. was put under the ban of the empire, but afterwards recovered his possessions; and his son, Charles Albert, in 1742, was raised to the imperial throne. On the death of his son, Maximilian Joseph, the house of Bavaria became extinct, and the electorate was suppressed. On this event Austria wished to annex Bavaria to her dominions, but her pretensions were opposed by Frederick of Prussia.

Bavaria was early and deeply involved in the French revolutionary wars. In 1799, Moreau found means to conclude a treaty for a cessation of hostilities, at a moment when Austria was threatened with invasion. The peace of Campo Formio increased the influence which France had sometime before begun to exert over her. After the victory of Hohenlinden, and the succeeding peace of Luneville, her subjection to France was complete; and as the reward of her alliance, she was, in 1806, elevated to the title of a kingdom, and extended by the accession of Tyrol, and several other provinces. In the same year, Bonaparte's step-son, Eugene Beauharnois, married Augusta Amelia, a princess of the reigning family of Bavaria. But the connection between these two countries, now strengthened by so many ties, was soon to be unbound by the operation of an unforeseen cause. The loss of her army in the horrible retreat from Moscow, in 1813, and the hatred inspired by the tyranny of Bonaparte, paved the way for this event. Soon after it she united and acted in concert with Austria. During the alliance against the lawless ambition of France, Bavaria, with an army of 60,000 men, powerfully joined the allies with a cordial co-operation: And on the success which crowned their exertions, and the negociations by which they were followed, Bavaria has recovered her rank and her independence among the states of Europe. She is to receive her share of the contribution money paid by France; the title of kingdom is confirmed, and the king is to possess the grand duchy of Wurtzburg, as it was held by the archduke Ferdinand of Austria, and the principality of Aschaffenburg, as it made part of the duchy of Franconia.

BAUHIN, John and Gaspard, two eminent botanists of the 16th century. John, the elder brother, was born at Lyons in France, in 1545, removed to Basil with his father's family, was appointed professor of rhetoric in that university, and for the last forty years of his life, which terminated in 1613, he was physician to the Duke of Wirtemberg at Montbelliard. The great botanical work, *Historia Plantarum*, &c. in 3 volumes folio, which was the labour of great part of his life, was not published till 1651.

Gaspard Bauhin, who was born in 1560, and died about the same time with his brother, practised as a physician at Basle; was at first professor of Greek, and afterwards of anatomy and botany, and was the author of *Pinax Theatri Botanici*, &c. or an index of the plants referred to or described by the ancient botanists. The names of John and Gaspard Bauhin, are still venerated by the lovers of botany, and hold a conspicuous place among those who contributed to revive and promote botanical knowledge.

BAUHINIA, Mountain Ebony, a genus of plants so denominated to commemorate the illustrious botanists, the brothers Bauhin, and belonging to the Decandria class.

BAXTER, Richard, an eminent English divine, was a native of Shropshire, and was born in 1615; and was not more distinguished by the extent and popularity of his writings, than remarkable for the scanty opportunities which he enjoyed of acquiring the elements of literature and science. Unaided by the instructions and discipline of any public seminary, he is indebted for his reputation to the force of his own genius, and the unceasing exertions of patient and laborious industry. His elementary studies were directed by his father, and other private individuals, in the progress of which early indications appeared of a contemplative mind, and a strong bias to literary pursuits. In his eighteenth year he visited London, with a recommendation to the master of the revels, for the purpose of obtaining some employment at court; but the bustle and pageantry of the scenes which he witnessed were ill-suited to his temper and thoughtful habits, and after a month's absence he returned with a double relish to his former studies. Admitted to ordination five years afterwards, he was first an assistant at Bridgenorth, and in 1640, he was appointed vicar, or stated preacher at Kidderminster, where he exercised his ministerial functions with the most exemplary diligence and remarkable success.

The civil dissensions which soon after distracted the kingdom, and involved it in scenes of bloodshed, drove him from his residence, and forced him to seek an asylum in various quarters of England. He joined the parliament, became chaplain of a regiment, and was always zealous and active in the suppression of turbulence; he seems to have been greatly respected by those in power, was employed to preach before the highest authorities; disapproved of revolutionary principles, and, after the restoration, he was appointed chaplain to Charles II. But although he was in much favour with that monarch, was consulted on the plans for settling the affairs of church government in Scotland, and was offered his choice of preferments in that part of the kingdom, and even, it is said a bishopric in England,—as he stood forward among the non-conformists, he suffered severely from the oppressive measures of the times, and was subjected to fines and imprisonment. He died in 1695, when he had reached his 76th year.

"Richard Baxter," says his biographer, "was a man famous for weakness of body and strength of mind; for having the strongest sense of religion himself, and exciting a sense of it in the thoughtless and profligate; for preaching more sermons, writing more books, and engaging in more controversies than any other non-conformist of his age. He spoke, disputed, and wrote with ease; and discovered the same intrepidity when he reproved Cromwell and expostulated with Charles II. as when he preached to a congregation of mechanics." His works were collected in four volumes, and have been abridged and published in a more compendious form. *The Saints Everlasting Rest; Call to the Unconverted*, of which 20,000 copies were disposed of in a single year, and which was translated into all the European languages, and even into the Indian tongue; *Poor Man's Family Book; Dying Thoughts, and Narrative of his own Life and Times*, are still popular; and the commendation of Baxter's works by Dr Johnson, is worthy of notice: "Read any of them," says the great moralist, "they are all good."

BAXTER, Andrew, a metaphysical writer, was born at Aberdeen about the year 1687, educated at the university of his native city, and seems to have been chiefly employed as a travelling tutor. As an author he is best known by his *Inquiry into the Nature of the Soul*, a work which attracted the notice of the learned. The later years of his life were spent in studious retirement at the sequestered village of Whittingham in East Lothian, in Scotland. He died in 1750.

BAYEN, Peter, a French chemist of some celebrity, was born at Chalons in 1725, studied pharmacy under an apothecary at Paris, and during the seven years war in Germany held the place of apothecary to the army. He was afterwards engaged at the public expence, to analyse the mineral waters of France; but although he was disappointed in the prosecution of this agreeable undertaking, he continued his chemical researches, and directed them to other objects; and he was fortunate in the discovery of the important fact, that the excess of weight gained by a metallic substance during calcination, and its change into the state of oxide, is owing to the absorption of air, and thus led the way to the final overthrow of the celebrated phlogistic theory. He died in 1798.

BAYEUX, a town of the department of Calvados in France, contains a population of about 10,000, and has some trade in leather. It is celebrated for a magnificent cathedral, and not less so for a famous piece of tapestry, executed by Matilda, the wife of William the Conqueror, and representing the history of the conquest of England. This precious relic, which is nearly 150 yards in length, and about two feet in breadth, was removed to Paris during the revolution, and engravings of it have been published in Ducarel's *Anglo-Norman Antiquities*.

BAYLE, Peter, the celebrated author of a historical and critical dictionary, was born 1647, at Carla in France, where his father was minister of a protestant congregation. The questions which, even in childhood, he proposed to his parents for solution, displayed a mind of superior capacity, and inspired the hope of future distinction. His father superintended his education till he was 19 years of age, and then sent him to the academy of Puylaurens, where, such was his love of learning, that he devoted even his hours of amusement to study. This over exertion induced a disease which threatened his life, and for some months interrupted his pursuits.

In 1669, he entered the university of Toulouse, was admitted a student of philosophy in the Jesuits' college, and to the inconsolable grief of his family became a convert to the Catholic creed. After a short stay he left Toulouse, and returned to his former faith; and his friends, perhaps dreading a relapse, sent him instantly to Geneva. Here his genius and his learning soon procured for him distinction and patronage. Mr Basnage, in particular, was zealous and active and persevering in promoting his interest. Through his recommendation he was tutor in three different families, which a discontented temper made him in quick succession unnecessarily exchange, complaining first of the seclusion of the country, and then of the unhonoured condition of a preceptor. When the philosophy chair of the Protestant academy of Sedan became vacant, Mr Basnage induced him to be a candidate, and, in a comparative trial, he took the place from all his competitors. He was elected to this office on the 2d November, took the oaths on the 4th, and began his lectures on the 11th of the same month, 1675. In this situation Bayle was associated with Jurieu, who was professor of divinity.

His lectures were much admired, and he was still rising in reputation, when, in 1681, the academy of Sedan, along with all the other protestant institutions in France were suppressed by the government. A few months after this event, a school similar to that of Sedan was instituted at Rotterdam, both for him and his colleague.

The great comet of 1680 gave rise to Bayle's first publication. Its appearance and eccentric motion had been viewed with alarm, as the harbinger of some signal calamity, and Bayle wrote a book to assure the world that comets afford no indication of divine displeasure. In defence of the Reformation, he next composed a criticism of Maimbourg's History of Calvinism. Jurieu wrote on the same subject, but was little noticed by the public,—a circumstance which is said to have excited in his mind a dislike to his rival which rankled into hatred.

In 1684 he commenced a literary and critical journal, entitled *News from the Republic of Letters*. This was deservedly a popular work; and in its second year, when he first inscribed it with his name, he was honoured with letters of approbation from most of the learned societies of Europe. Through the instigation of Jurieu, and the removal of his friends from power, Bayle was, in 1693, deprived of his professorship, with all its emoluments. But his own fortitude, and the esteem of the public, which was now eagerly testified in his favour, enabled him easily to sustain this calamity. The first volume of his Historical and Critical Dictionary, the scheme of which he had advertised some years before, was now in the press, and he was delighted with the leisure he enjoyed to superintend its printing. The moment this work appeared it was instantly bought up, and loudly praised. A new edition in four volumes was published in 1701. And soon after he sent a less elaborate work into the world, entitled, *Answers to the Questions of a Country Gentleman*, containing much of the lighter matter of the Dictionary.

From his first appearance as an author, Bayle was deeply involved in controversy, and the publication of his Dictionary served to increase the number of his antagonists, and to multiply the topics of debate. Jurieu, actuated by a malignant spirit, was always ready to decry whatever he advanced; Le Clerc and others disputed with him concerning the nature of things and the origin of evil; and the consistory of the Walloon church of Rotterdam cautioned him to be on his guard in future respecting the doctrines which he ventured to publish. He was busily employed in the composition of explanations, defences, and rejoinders, when he was seized with a decay of the lungs, of which he died on the 28th December 1707. He left some property to his relatives, and bequeathed some legacies to his friends.

Bayle was a man of frugal habits, and entirely devoted to study; he possessed a faithful memory, well furnished with all kinds of knowledge; but he seems to have had little skill in the management of his materials. His Dictionary, which is his greatest work, is thus characterised by himself:—"It is nothing else," says he, "but a confused compilation of passages tacked together,—a medley of proofs and discussions,—a criticism of many errors,—and a long train of philosophical reflections." Voltaire, who has given him a place among the illustrious authors that adorned the age of Louis XIV. says "he was a great logician rather than a profound philosopher." The universal adoption of the inductive method of philosophizing has now entirely exploded many theories on which Bayle expended a large portion of time and ingenuity; and it is hoped, that however men may speculate of *providence, foreknowledge, will, and fate*, they shall not, for the sake of opinions, the truth or falsehood of which mere reason can never determine, again involve the world in a war of words.

BAYONET, a short dagger, which is fitted to the end of the musket, so that the whole instrument may be used either for attack or defence, is supposed to derive its name from Bayonne, where, it is said, it was first manufactured, and was introduced into the French armies about the end of the 17th century. The use of the bayonet was revived and improved by the great Frederick of Prussia, and its powerful effects in the British and French armies during the late wars are well known.

BAYONNE, the largest town of the department of the Lower Pyrenees in France, is finely situated on the banks of the Nive and Adour at the place where they unite their streams, and about three miles from the sea. The town is defended by fortifications and a citadel. The population is about 13,000; the trade with Spain is considerable; woollen cloths, silks, cottons, and hardware, are exchanged for wool, wine, and oil; and masts and spars are conveyed down the rivers from the Pyrenees, to be exported to different parts of France. The Basque or old Biscayan language, and part of the dress, are still in use among the common people of Bayonne.

BAYREUTH, or BAREITH, is the chief town of the margravate of the same name in the circle of Franconia, is commodiously situated on the banks of three rivers, contains about 10,000 inhabitants, and was formery the seat of thriving manufactures.

BAZAR, a term of frequent occurrence in the narratives of oriental travellers, signifying the market places of eastern countries, and derived, it is said, from the Arabic word denoting *sale*, or *exchange of goods*. Separate edifices are appropriated to this purpose; and in the Persian and Turkish dominions some of the bazars or market places are spacious and magnificent structures.

BEAR. See *Ursus* under MAMMALIA.

BEARD, the hair which grows on the chin and contiguous parts of the face of adults. Among the ancient Greeks and Romans, at least in the earlier periods of their history, it was the practice to wear the beard, and it seems to have been an object of great veneration. The Greeks began to shave the beard about the time of Alexander the Great; and the Romans, in the 454th year of the city, when barbers were brought from Sicily for the purpose. It is curious to observe the diversity of caprice and fashion in cutting off the beard, or in permitting it to grow. Ecclesiastics have been sometimes enjoined to wear the beard as a mark of gravity, while at other times it has been forbidden; and in different churches opposite practices have prevailed. The Persian Mahometans shave the upper lip; but the Arabs, who are attached to the same faith, preserve their beards with the most scrupulous care. The Roman slaves wore the beard and hair long, and were only shaved when they obtained their freedom; but the Turkish slaves in the Seraglio are shaved as a mark of servitude. The Greeks shaved the beard, and cut off the hair as a token of mourning; but the Roman expression of sorrow and affliction was to permit the hair and beard to grow.

BEARN. See BERNE.

BEATON, DAVID, archbishop of St Andrew's and primate of Scotland, during the reign of James V. and the minority of Mary, was born in Fife in 1494, studied, under the direction of his uncle archbishop of St Andrew's, first at that university, and then at Paris, and entered into orders as soon as he had attained the canonical age. The Duke of Albany, regent of Scotland, appointed him resident at the court of France, and his uncle made him rector of Camp-

Beaton.

sie and abbot of Aberbrothick. On his return from France he was invested with the privy seal of Scotland, and employed, along with Sir Thomas Erskine, in the negociation of a marriage between King James and the daughter of the king of France. Their nuptials were solemnized at Paris, January 1537, and the royal bride was conducted by Beaton to the court of Scotland in the succeeding May. But as this princess did not long survive her marriage, Beaton was again despatched to France to obtain for the king, Mary, the daughter of the duke of Guise; a mission which he executed with success.

While he lived at the French court, he had the address to insinuate himself into the good graces of Francis, and to become master of the whole of his political system; a circumstance which enabled him afterward to rule his sovereign, and to raise himself; and by his entire devotion to the interests of the church, he obtained her dignities in great number, and in quick succession. He was consecrated bishop of Mirepoix, raised to the dignity of cardinal with the title of St Stephen, and soon after installed archbishop of St Andrew's and primate of Scotland.

On this elevation, the dark, designing, and bloody spirit of bigotry with which his mind was actuated began to disclose itself in the cruelty of his conduct. He summoned his clergy together, denounced the reformers as heretics, and proscribed many of the nobility. But the intervention of the king's death saved them from suffering, and diminished for a while the archbishop's power. After this event, he exhibited a document bearing the late king's signature, nominating himself, the Earls of Argyle, Huntly, and Arran, joint regents of the kingdom during the long minority of Mary. Historians assert that this paper was a forgery. But it did not serve his ambitious purposes; for Arran was chosen regent, and the archbishop was imprisoned in the castle of Blackness. But he soon obtained his liberty, was re-admitted into the council, promoted to the office of chancellor of the kingdom, and appointed the pope's legate in Scotland. With this accession of power he recommenced his persecution of the reformers. George Wishart, a celebrated preacher among the protestants, soon became his victim; through his means he was condemned to the flames; and the cruel cardinal, with a barbarous joy, beheld his martyrdom from the windows of his own castle.

But he had now incurred a general detestation, and the hand of the assassin was at hand to terminate his wicked career. Norman Lesley, son of the Earl of Rothes, with about sixteen associates, seized on his castle in the morning of the 29th May 1546, and having rushed into his chamber they dispatched him with their swords, and suspended him over the very window whence he had lately witnessed with such savage satisfaction the calm and resigned death of Wishart.

Cardinal Beaton was a man of great talents, which were well fitted for public business; but he had little learning, and still less virtue. His pride was overbearing, his ambition was unbounded, his manners were polluted, and his bigotry was bloody. While he lived he commanded great influence, amassed great wealth, and left a numerous illegitimate offspring.

Beattie.

BEATTIE, James, a distinguished author, both in poetry and prose, was born at Laurencekirk in the county of Kincardine in Scotland, in October 1735. Death deprived him of his father in early childhood, a loss which the fraternal affection of his brother David, then in his 18th year, greatly alleviated. The parochial school of Laurencekirk, which had acquired a high degree of celebrity from Mr Ruddiman, of philological celebrity, formerly its master, was at that time taught by a Mr Milne, a man of classical information. Under him young Beattie commenced his education, and was initiated in the knowledge of Greek and Roman literature. In 1749 he offered himself a candidate for one of the bursaries, or small annual stipends, in Marischal college, Aberdeen; which, after a comparative trial with the rest of the competitors, was bestowed on him as the reward of superior merit.

Having pursued his studies for four sessions, and completed the course prescribed by his college, he was admitted to the degree of master of arts; and, in consequence of the reputation for learning which he had already acquired, he was soon after elected parochial schoolmaster of the parish of Fordoun, adjacent to that of his nativity; a situation humble and secluded; yet most favourable for confirming his studious habits, and for maturing his poetical genius. Here he spent five years, procuring the grateful confidence of his employers by a diligent and able discharge of his duty; commanding the respect of the neighbourhood, by the number and the nature of his attainments; and gaining the love of all his associates by the purity and gentleness of his manners.

In 1757 he was an unsuccessful candidate for the office of usher in the grammar-school of Aberdeen; but on a second vacancy in the following year he was invited to accept of it, with the assurance of being preferred to the rectorship when that situation, then held by an old man, should become vacant. He now returned to Aberdeen, the seat of his Alma Mater, with which every man of genius has so many pleasing associations; and as he had himself profited under her fostering influence, he was, to his own amazement, elevated to the rank of sustaining her character for learning and science, by being appointed, through the interest of his friends, to the professorship of moral philosophy and logic in the year 1760, and the 25th of his own age.

At an early period he had begun to publish little pieces of poetry through the medium of the Scots Magazine, and the applause which had been bestowed on those juvenile productions encouraged him to collect them into a volume; he also published, about the same time his Essay on Poetry and Music; a work which forms an excellent introduction to the study of criticism, and which, previous to its publication, had been read and approved of in a literary society, of which Drs Reid, Campbell, Gerard, and other learned men connected with the university, were members, and Mr Beattie's constant companions. In 1767 he married Miss Dun, the only daughter of the rector of the grammar-school of Aberdeen. His union with this beautiful and accomplished young lady, which was formed under the auspices of ardent and mutual affection, and which opened a fair prospect of great and long felicity, proved, in consequence of calamities as unforeseen as they were severe, a source of bitter and heart-rending anguish.

The course of Mr Beattie's academical lectures led him to investigate the principles of human thought and action, and to discuss the questions which a subject so interesting had suggested; and, alarmed at the pernicious progress of infidelity, he formed the resolution of endeavouring to demolish the towering system of scepticism, which Hume and Berkely had built on the ideas of Aristotle, by shewing that it rested on no better foundation than a mere assumption, destitute of evidence. With this design, he published in 1770, his *Essay on the Immutability of Truth;* a work which quickly brought him a great accession of celebrity. In England, especially, it was hailed by the friends of revealed religion, and of the certainty of human knowledge, as well as of human obligation, as an opportune and effectual refutation of error. It was loudly applauded for the elegance of its composition, the perspicuity of its arrangement, and still more for the utility of its tendency. The friends and admirers of Mr Hume, indeed, then living in Edinburgh, regarded the whole as a personal attack on that elegant author, dictated by malignity; Dr Priestley also, and some others in England, found fault with its principles; but the hoarse murmurs of censure and dissent were little heard or regarded, amid the clear and continued peals of applause with which it was received; and so rapid was its sale, that a new edition was quickly put to the press. In the same year he published the first canto of the Minstrel, the design of which, as explained by himself, "was to trace a poetical genius, born in a rude age, from the first dawning of fancy, till that period at which he may be supposed capable of appearing in the world as a minstrel, or itinerant musician;—a character, which, according to the notions of our forefathers, was not only respectable but sacred."

On his first visit to London, Mr Beattie was unknown, and of course unnoticed; but when, in the autumn of 1771, he spent some time in that city, the reputation of his great talents and elegant taste, exerted in the cause of truth and virtue, opened to him a ready access into the most select circles of literary and scientific society. At the house of the celebrated Mrs Montague he met the most distinguished characters of the age. And during a subsequent visit, so general was the interest which his works had excited, that he was enabled to enrol among the number of his acquaintances and friends most of the learned men of London, many of the dignitaries of the church, some of the peers of the realm, and even the king and queen of the country. The university of Oxford conferred on him the degree of doctor of laws; Sir Joshua Reynold's painted his portrait; and government bestowed on him an annual pension of L.200.

But the beneficence of his friends in England had not yet exhausted itself. He had often been solicited to take orders in the church, with the assurance of preferment; and, to tempt his compliance, a living worth L.500 a year was offered him in 1774. But this flattering offer, as well as a professorship in the university of Edinburgh, he declined, lest it should be said he had written under the influence of mercenary motives, and he should farther provoke the spirit of opposition, which had already displayed itself—circumstances which tend greatly to enhance his character. From this time Dr Beattie was employed in the discharge of his academical duties, and in raising a reputation already proudly pre-eminent, by additional publications. But his days of delight were now drawing to a close;—the irritability of Mrs Beattie's nerves, and the caprices of her temper, arising from a mental malady inherited from her mother, and which at last subsided into settled insanity, had for many years greatly interrupted his domestic tranquillity. His eldest son, an amiable and an accomplished youth, who had been associated with him as his assistant and successor in the college, was seized by a consumption, which, after a lingering illness, brought him to the grave just as he had attained the verge of manhood. His afflicted father, inconsolable, indulged his grief by drawing up an account of his too short life, by inscribing an epitaph on his tomb, and by dreaming of the grave which lay beneath. The death of his youngest son, in 1796, left him childless; and a stroke of the palsy, which nearly deprived him of speech and motion, crowned his calamities. After a long period of helpless imbecility, death, on the 8th of August 1803, put a period to his sufferings. He died in the 68th year of his age, departing in peace, in the hope of immortality and happiness.

In personal appearance, Dr Beattie was of the middle size, strongly made, and inclining to corpulency. The complexion of his mind will be found in his works, which disclose the poet and the philosopher, the good man, and the true Christian. His Minstrel is a poem remarkable for simplicity and sweetness of language, for purity and pathos of sentiment, and for richness and truth of description. And a most interesting piece of information is, that in the character of Edwin he has delineated himself as he was in his younger days. "I have made him (he says, in one of his letters) take pleasure in the scenes in which I took pleasure, and entertain the sentiments similar to those of which, even in my early youth, I had repeated experience." His prose writings are voluminous. Of these, his Essay on Truth,—on Poetry and Music,—on Laughter and Ludicrous Composition,—on Classical Learning,—on Memory and Imagination,—on Dreaming,—on the Theory of Language,—on Fable and Romance,—on the Attachments of Kindred,—and his Evidences of Christianity, and Elements of Moral Science, display many instances of a vigorous understanding, of a discriminating judgment, of extensive information, of sound criticism, and of sincere and unaffected piety, set off with an elegant and animated stile; so that his works are, perhaps, as well fitted as any in the language for initiating the young student in the various branches of mental philosophy. In his Essay on Truth he has been charged with railing rather than reasoning, and with having interlarded his language too profusely with the pungency of acrimony for the uninterrupted coolness becoming a philosophical discussion. But in this (whether defensibly or not is a different question) he acted from principle, not from passion. He viewed his antagonists in the light that we view the thief or the robber, who endeavours to deprive us of our property; and conceiving that they had intentionally attempted the most irreparable of injuries, he was of opinion that their attacks ought to be repelled with a warm earnestness of manner. But whoever will read his letters on this subject, contained in Sir William Forbes's Memoir of his Life, will soon be satisfied that he was incapable of cherishing a hostile disposition in his heart.

BEAVER, a remarkable animal, on account of its singular habits, and the value of its fur in the manufacture of hats. See *Castor*, under MAMMALIA.

BEAUMARIS, the chief town of the isle of Anglesea in South Wales, stands at the north entrance of the strait of Menai, consists of two spacious streets, includes a population exceeding 1500, and is 254 miles north-west from London. The harbour affords safe and commodious anchorage to ships in six or seven fathoms water; but the trade is less considerable than in former times. The castle was built in 1295 by Edward I. to overawe the inhabitants; and from that time the town dates its origin as a place of importance.

BEAUMONT and FLETCHER, two celebrated English dramatic writers, whose names are always associated as the joint authors of a great number of plays which long kept possession of the stage, flourished in the early part of the 17th century. More than 50 separate pieces were the fruits of their united labours in this singular literary copartnery. A folio edition of their plays was published in 1679, another in 1711, in seven volumes 8vo., a third in 1751.

Francis Beaumont was descended from an ancient family in Leicestershire, and was born about the year 1586. His father and grandfather held high official situations in the legal establishment of the country. The latter was master of the rolls, and the former was one of the judges in the court of common pleas. Young Beaumont had the benefit of an university education at Cambridge, and was admitted a student in the Inner Temple; but it would appear that he had early abandoned the pursuits of law for the more attractive charms of the dramatic muse; for he died in 1615, before he had completed the 30th year of his age.

John Fletcher, the friend and poetical coadjutor of Beaumont, was the son of the bishop of London, was born in 1576, and was also educated at Cambridge, where he was distinguished by great proficiency in his studies, and was reputed an accomplished scholar. When he had reached the 49th year of his age, he fell a victim to the plague which ravaged the metropolis in 1625.

BEAUSOBRE, ISAAC DE, an eminent French protestant divine, was born at Niort in Switzerland in 1659, and was descended from a family which had fled from France about the time of the dreadful massacre of St Bartholomew in 1572. He was educated at the college of Saumur, and at the early age of 22 was appointed minister of a protestant congregation in France. About three years after his admission, severe measures were adopted against the protestants, and his church was shut up by an order of government; but an excess of zeal led him to break off the royal seal, and, to avoid the consequent punishment, he fled first into Holland, and finally, in 1694, he found a safe asylum in Berlin, which became the fixed residence of his future life. His talents and acquirements as a man of learning and a preacher, soon raised him to merited distinction. He was appointed royal chaplain, inspector of the French college, and superintendant of the French churches of the diocese. He died in 1738, at the venerable age of 80. His principal works are, a *History of the Reformation*, which occupied 40 years of his life, and was published at Berlin in 1784 and 1785; the *Critical History of Manichæus and Manicheism*, an elaborate and profound disquisition. His sermons were peculiarly distinguished for original thinking, elegant diction, and appropriate and forcible illustration.

BEAUTY, is that quality or condition of objects by which they are fitted to excite agreeable emotions or pleasing ideas in the mind. The term appears to have been originally applied to *colours*, but was gradually extended to other physical qualities, and in modern times embraces almost every thing, whether material, intellectual, or moral, which occasions a certain feeling of complacency and tenderness, when contemplated by the understanding. Thus we speak with equal freedom of the beauty of a carnation, a fine woman, a spaniel, or a lap-dog, a piece of music, a mathematical theorem, a philosophical discussion, the self-denial of Scipio, or the philanthropy of Howard. What is there common to all these cases, and a thousand more, which can vindicate the employment of the expression, and the application of its kindred epithet, beautiful? or, on the supposition that there is really nothing common to them, what is that peculiar affection of mind which is excited on so many very different occasions? These are among the most intricate questions in metaphysical science, or, to use a more appropriate phrase, respecting the knowledge of human nature, and have received almost as many answers as there are diversities of character in mankind,—a clear evidence, it is conceived, of gross and very general misunderstanding of our constitution, and of the substitution of mere reasoning, conjecture, hypothesis, and partial observation, in the room of deliberate and circumstantial inquiry. A very superficial view of the ingenious theories and splendid speculations on this subject, or, at once to characterise them, *beautiful* absurdities which have successively jostled one another out of the schools, would be sufficient to appal any man of common sense, who had *notwithstanding* a little anxiety to be informed by the learned why he is pleased with some things and not with others, and to ascertain the reason of his neighbour and himself so frequently disagreeing about the shape of their hats or the colour of their waistcoats, though they are perfectly of the same mind in politics, and express equal admiration of their parish church. But an enumeration of errors is not unimportant, if any way calculated to shew the vanity of dogmatism, and to deter genius from the misapplication of labour.

Theories.—The first notion of beauty, or *theory of the beautiful*, we shall notice, is that which conceives this quality to consist in utility or fitness, that is, the

Beauty.

suitableness or adaptation of objects to the purposes for which they are designed. This is a very ancient opinion, and may easily be accounted for. The savage who had been ingenious enough to erect a hut which defended him from the inclemencies of the weather, or to hollow out the trunk of a tree, so as to enable him to cross the river which limited his range, or even to sharpen and point the fragment of a rock, by which he was emboldened to assail the tusk-armed inhabitant of the forest, would naturally contemplate the product of his skill with feelings of delight and pleasure. His conception of the beautiful, it is highly probable, would be almost coexistent with his success, and the very colour and form of his dwelling, his vehicle, or his instrument, would ever after be identified in his mind with the pleasurable consciousness of something excellent. It may be freely granted, therefore, that the perception of fitness and utility is reconcileable with the notion of beauty. But that this does not exclusively constitute beauty is certain, from the simple fact, not to enter on any process of reasoning, that many things are thought beautiful, that is to say, occasion the emotion of beauty, which are totally unfit for any one valuable purpose whatever. Besides, it is no less true, and no less destructive of this theory, that in civilized life there is an immense number of objects, which, though abundantly useful, are far enough from exciting any agreeable ideas.

Unity of parts.—Very nearly allied to this opinion, and liable to modifications of the same objections, is the theory which resolves beauty into the expression of unity, that is, concord, or harmoniousness of parts, implying design and determination. Perhaps the notion maintained by some of the followers of Leibnitz, that beauty consists in perfection, is not very dissimilar. Father Buffier is the chief advocate of this last system, which professes to determine a very intricate question, long debated in the schools, what is the *standard* of beauty? The ostensible reply is, that which is most common to all the individuals or members of a species. But it is miserably defective,—many things being reckoned beautiful which are neither common nor yet perfect; and, on the other hand, the things or qualities of things which are most common to individuals, to species and genera, being in reality least productive of the emotions of beauty.

Arrangement.—Another theory asserts beauty to consist in the symmetrical arrangement and relation of parts. This is strikingly exemplified in some of the works of nature, and many of the productions of art, but obviously excludes an immense variety of objects which most men have agreed to be beautiful. The doctrine of certain proportions constituting beauty, without respect to any ultimate design or purpose, is a branch of this system which has long been popularly admitted in architecture. But its influence has rapidly declined of late years, and is now almost entirely confined to the more vulgar practitioners of that noble art.

Of five elements.—A combination of some of the preceding theories, with slight additions, has been attempted by some foreign writers, who determine beauty to be made up of five elements, variety, unity, regularity, order, and proportion.

2

Hutcheson's theory.—Dr Hutcheson of Glasgow broached the idea that beauty was nothing else than the union of variety and uniformity, as perceived by a peculiar internal sense. This, too, had its day, totally supposititious as it was, and in reality opposed to the result of the most familiar observations. But in our judgment, it is the appeal to facts as to the objects themselves which are generally considered beautiful, that decides against his system, and not the mere circumstance of his proposing the introduction of an additional faculty in order to explain the phenomena. Dr H. has the merit, not immaterial, we apprehend, of venturing beyond the precincts of scholastic philosophy, and anticipating in principle, though by no means in object, one of the peculiarities of an extensive system, which has threatened, since his time, to bring about a total revolution in metaphysical science. We allude to the labours of Gall and Spurzheim, of which we shall elsewhere have occasion to speak more particularly.

Hogarth's.—Hogarth, the painter, considered variety as the most material constituent of beauty. But he admitted the influence of fitness, uniformity, simplicity, intricacy, and quantity. This ingenious but whimsical man, is remarkable for having pitched on a certain curve, which he has chosen to denominate the *line of beauty*. An approximation to it is unquestionably found in many objects capable of giving agreeable emotions. But the pleasure derived from them as objects of taste, is, in all probability, resolvable into the notions of ease, tenderness, and delicacy, which they occasion. Now these are utterly unsuitable to the character of other objects, which are nevertheless thought beautiful. This branch of the theory, therefore, is erroneous, and indeed the whole of it is partial, incomplete, and unsatisfactory.

Burke's.—No less a man than Edmund Burke blundered egregiously in fabricating a *theory of beauty*, though certainly very successful in demolishing some of the opinions which he meant to supplant by his own invention. Beauty, according to him, is a certain quality, or a combination of qualities, in bodies, by which the mind is operated on through the medium of the senses, and a kind of languor, or relaxation of fibres is produced. Smoothness of surface, delicacy of texture, gradual variation of outline, and smallness of size, as might naturally be expected, are some of the physical properties or conditions of bodies connected with the quality assumed in this theory. It is almost needless to say, that this is a very imperfect enumeration of the sources of the beautiful. But even though it were complete, it would as much fail to explain what beauty is, as an enumeration of the occasions on which gout or an ague take place would be insufficient to point out the nature of those diseases. Moreover, the supposition of a relaxation of fibres is confirmed in only a very few of the cases in which the emotions of beauty are experienced.

Diderot's.—It is, if possible, the still more erroneous and fantastic opinion of Diderot, that the beauty of objects consists in the power of exciting in the mind the idea of *relation*; or, in other words, that our conception of the beautiful is identical with the act of comparing the relations between different objects, and is of variable strength in proportion to the number and distinctness of the relations discovered. Among the objections to this theory, it is perhaps enough to mention, that the discovery of relations is not always even a source of pleasure, so far from being itself the very essence of beauty; and that there are many objects which instantaneously excite the agreeable emotions of taste, in certain minds, or on persons of certain character, although there do not take place in them the slightest effort or wish to form any comparisons whatever; farther, if this theory were true, it follows, that many ugly or positively disagreeable objects should necessarily become sources of pleasure, inasmuch as they are equally prolific of relations with those which bear a very different character.

Mr Alison's.--The cautious examination of these and other theories, and attentive consideration of his own experience, have conducted Mr Alison to a very different view of the nature and sources of beauty. According to this eloquent writer, beauty is not the result of any of the qualities of bodies, simply contemplated as such, but of these qualities as invested with new and totally disimilar powers, by association with our own affections, emotions, and ideas. The mind, in fact, appears to be considered in this system as forming a connexion with material qualities, in the progress of its intercourse with the external world, and to be occasionally engaged in operating on itself, when these qualities are either directly presented to the senses, or are brought before the imagination by a process of memory. Such, in few words, is the essence of a theory, which, of late years, has obtained the greatest currency in the literary world. It is stated, exemplified, and defended in a very elegant and pleasing manner, in the "Essays on the Nature and Principles of Taste," to which we must necessarily refer the reader. Mr Payne Knight, Mr Dugald Stewart, and the editor of the Edinburgh Review, have lent their support to its most peculiar features, but with sundry modifications, some of which indeed appear not a little at variance with the fundamental proposition. This is particularly the case with the first-mentioned author, who contends for the existence of some portion of beauty at least, altogether independent of the associating principle. Against this supposition, the reviewer has inveighed as quite heretical; though he himself, of course, admits the power of pleasing our senses to exist in certain qualities of bodies, as, for example, colour and sound.

Objections.—To a theory, supported as this has been on such high authority, and rendered captivating as it is by a felicity and splendour of decoration beyond all precedent in metaphysical compositions, we shall not scruple to object. The grounds of our demurring shall be stated in the form of distinct propositions, which we leave for the reader's consideration, rather than assume the more dignified but less modest appearance of an essay professing to decide the question.

In the first place, this theory seems to us too much confined to material objects, and to exclude the consideration of two very important and scarcely less extensive classes of objects, those of an intellectual and moral nature, which are notwithstanding perfectly well known to be highly productive of beauty.

2dly, A principle is assumed in this theory, which, though admitted in certain metaphysical writings to be a part of our constitution, is, in our judgment, nothing else than a form of expression to denote a series of facts, and cannot be proved to have any existence in the mind as a separate or distinct faculty. We mean the association of ideas,—which, according to this theory, the mind not only has the power of exercising within itself, if the phrase be allowed, but also of extending, in some incomprehensible manner, to external objects. The language of one of the advocates of this theory, when alluding to this power, even granting something in the way of poetic licence, is singularly incautious: "The beauty which we impute to outward objects, is nothing more than the reflexion of our inward emotions, and *is made up entirely of certain little portions of love, pity, and affection, which have been connected with these objects, and still adhere as it were to them,* and move us anew whenever they are presented to our observation." With equal propriety might a physiologist assert, that the nutritive quality of certain bodies used as food, is nothing more than the reflexion of our own internal functions, and is made up entirely of certain little portions of cartilage, membrane, and muscle, which have been connected with these aliments, and still adhere as it were to them, when they are taken into the stomach!

3dly, The theory appears inconsistent with itself. The fundamental proposition with which it sets out, that there is no beauty in the external objects themselves, but merely as they are operated on or new-modelled by association, we imagine excludes beauty altogether, except in so far as our own emotions, affections, and ideas are concerned. In this respect it strongly resembles the hypothesis of Bishop Berkely, by accurately reasoning on which one comes to the comfortable conclusion, that there is no external world at all, and that we have no satisfactory evidence of the existence of any thing but our own minds and the ideas which pass through them. To defer the emotions of beauty till certain associations be produced, and to affirm or imply that these associations are formed because of the antecedent or concomitant experience of something agreeable or pleasing, seems no less contradictory in itself as a logical proposition, than irreconcileable with daily observation.

4thly, We are in many cases totally unconscious of any association of ideas having a share in the production of the agreeable emotions felt when certain objects are presented to us. In other words, the theory does not always apply, even admitting that so far as it goes it is well founded. Here we may remark, it is freely granted that the consciousness of certain ideas, or trains of ideas, passing through the mind, is one source, and that a fruitful and powerful one, of pleasure. But, on the other hand, it is contended, that we are sometimes *instantaneously* impressed with emotions of beauty, consequently before such associations have had time to present themselves; and in other cases, it may be added, the simple emotions of beauty may be experienced in spite of associations, which, if given way to, would be totally subversive of them, and destructive of pleasure. The theory, therefore, though in part true, is inadequate to explain all the phenomena, and cannot, agreeably to the precepts of sound philosophy, be held as the proper solution of the question. In our judgment, a single exception, fairly sustained, is conclusive against its claims to the honour of a law of nature.

Other objections of minor, but not inconsiderable force, are purposely omitted for the present. We shall conclude with barely stating the outline of another theory, derived from a system formerly alluded to, though, as far as we know, not contemplated by its authors. It involves some subjects of an intricate and curious, but highly important nature, to which there will be opportunities of afterwards calling the reader's attention. The merest suggestion is all that can now be hazarded.

More plausible theory.--The human mind consists of various powers, faculties, propensities, and sentiments, each of which is dependent on a certain condition and exercise of an appropriate organ seated in the brain. The different organs are connected together in such a manner, that they may be operated on, or may operate, either separately, that is, each by itself, or conjointly, in any variety of combination. They are not of the same dimensions, intensity, or power in different individuals, nor are they any way proportioned to one another in the same individual. Hence the immense diversities of character among mankind, and the variable and varying conduct and experience of the same persons, in different circumstances, or in the same or like circumstances in different periods of life. It is a law of our constitution that these organs are affected, and consequently their respective powers, &c. &c. excited by impressions from without, and also by various processes carried on in the system, during the course of organic and animal life. It is equally a law of our constitution, for which we can assign no reason but the will of Him who made it, that of these impressions and impulses, if we may so speak, some are agreeable, others disagreeable, and that their corresponding results are, therefore, relished by us or disliked. The five senses afford us familiar, but equally inexplicable examples. Certain tastes, smells, sounds, *visibles*, &c. are pleasing and displeasing, sometimes in spite of our own wills, and, except in a few cases, without our being able to give any reason why they are either one or other. Our *internal senses*, so to speak, are quite in the same predicament. There are certain adaptations of external objects to them, taking this phrase to comprehend every thing that may be subjected to our minds, which are productive of agreeable emotions, and these are either confined to one organ, or embrace several organs, according to circumstances and the character of the individuals. It is the diversity of character, dependent on what has already been mentioned, that gives rise to the various associations of ideas, so much insisted on in the preceding theory; and on the same principles may readily be explained both the concord and disagreement of mankind as to the objects of taste. The theory now suggested, it is proper to remark, does not admit the existence of any general powers or faculties known under the names of judgment, memory, and imagination, according to the systems of the schools. In place of these, it is conceived, that each of the special faculties or higher powers of the mind has its own judgment, memory, and imagination; and that these are dependent, in some hitherto inscrutable manner, on the degree, and, perhaps, kind of activity, of the respective organ. The theory would restrict the term beauty, and, of course, several other terms which are often used when speaking of the objects and nature of taste, to those faculties and powers which are so endowed. These are as numerous as the peculiar qualities of bodies, and the moral and intellectual powers of the mind. Each finds pleasure and the beautiful in its appropriate object, and may excite some other power or powers of the mind. Farther, there is a system of supremacy and subordination among these powers, intended, and plainly pointed out by the hand that made us; and it is only in reference to this, and deducible from it, that we can decide on a standard of taste. Finally, this theory, while it not only leads to mutual forbearance in things indifferent, as a polite and convenient expedient, but absolutely enjoins it as a law of nature, nevertheless accurately and imperiously specifies its limits; nor is it its slightest recommendation, that it confirms the connexion of mankind with one another and with the world in which they are placed, and irresistibly demonstrates their entire dependence on Him who created all things, and " in whom they live, and move, and have their being."

BECCARIA, Giambattista, a celebrated electrician, was born at Mondovi, in Italy, in 1716, and having completed the elementary parts of his education, he repaired to Rome at the early age of sixteen, for the purpose of assuming the monastic habit; and being admitted to a religious order, he commenced a regular course of study to improve and extend his knowledge. The bent of his genius drew him off from scholastic subtleties, and led him to pursue the more useful path of physical science. When he had finished his studies he was appointed to teach belles lettres in the college of Urbino, and executed the charge with ability and diligence. But although he was an ardent admirer of classical literature, and produced some elegant specimens of Latin poetry, he soon after relinquished the seductive charms of the muses, and devoted his labours to mathematics and natural philosophy. On these subjects he delivered lectures, first in the Royal college of Palermo and afterwards at Rome; and in 1748 he was appointed to the chair of natural philosophy in the university of Turin.

Beside other curious disquisitions in various departments of physical science, Beccaria entered deeply into the investigation of electrical appearances, and in 1753 published his Treatise on *Artificial and Natural Electricity*, which was translated into English in 1776. In the year 1774 he published the result of a laborious undertaking which he had completed ten years before. This was the measurement of a degree of the meridian in which he was charged by the celebrated astronomer Cassini with inaccuracy. On this subject, and on his Theory of Electricity, a controversy commenced; and in the latter period of his life he was a good deal occupied in defending his opinions.

The arduous labour and incessant fatigue to which he had been subjected in the measurement of the degree of the meridian induced a severe disorder, which in the year 1776 assumed an alarming appearance, and after repeated attacks, along with the accession of an intermittent fever, completely exhausted his strength under their accumulated pressure, and terminated his mortal existence about the close of the year 1781.

With all his talents and reputation, Beccaria enjoyed no great share of popularity among his countrymen. The coarseness of his manners was disgusting, and his excessive ambition of fame often excited jealousy. His seclusion from the world, which left him in ignorance of the ordinary modes of courtesy and forbearance, may perhaps in some degree account for his peculiarities. But the solid learning which he possessed, and the laborious researches in which he was engaged, raised him to a high rank among men of science, and procured for him the honour of being enrolled among the members of the Royal Society of London and of other learned bodies. Beside his favourite subject of Electricity to which a large share of his attention was devoted, he made improvements on the solar microscope, and on the pendulum, for the purpose of correcting the errors produced on the latter by its contraction and expansion from heat and cold, invented an ingenious formula for discovering the foci of lenses, made some curious remarks on the double refraction of Iceland crystal, and left behind him various treatises on astronomy and natural history.

BECCARIA, Cæsar Bonesana, Marquis of, the celebrated author of a work on *Crimes and Punishments*, was born at Milan in 1735, was initiated in the elements of literature and science at the Jesuits college in Parma, and afterwards devoted himself to mathematics, and particularly to the study of jurisprudence. His first publication was on the debased state of the current coin of the Milanese states; and at no very distant period it was followed by his *Treatise on Crimes and Punishments*, the most elaborate and most popular of all his literary productions. The Marquis Beccaria was also the author of various other works, chiefly connected with political economy, and he held various official situations in the state. He died in 1793.

BECHER, John Joachim, one of the earliest systematic writers on chemistry, was a native of Spires in Germany, and was born in 1625, was fortunate in being promoted to high official situations, as physician to the elector of Mentz and the elector of Bavaria, and counsellor to the emperor; and it is said that he was furnished by those distinguished personages with the means of carrying on his experiments in natural philosophy and chemistry. But he seems to have been of a restless disposition. His residence was often changed while he remained on the continent, and at last he repaired to London, where he died in 1682. His learning was various and extensive; and he was the first who applied chemistry in explaining the composition and relations of bodies. He was the author of numerous works on chemical subjects, the chief of which are his *Physica Subterranea*, and *Institutes of Chemistry*, all written in Latin. See *Boerhaave's Chemistry*, translated by Shaw.

BECCLES, a town of Suffolk in England, stands on the banks of the Wavenay, includes nearly 3000 inhabitants, who are only occupied in domestic manufactures, is composed of several streets diverging from a spacious central area, and, from the conspicuous station of the church, an elegant Gothic structure, exhibits a fine view of the windings of the river and the surrounding country. Beccles is 15 miles south-west from Yarmouth, and 108 miles north-east from London.

BECKET, Thomas A, archbishop of Canterbury, whose struggles for the supremacy of the church, and tragical death, form a striking feature in the history of the times, was the son of Gilbert Becket, sheriff of London, and was born in 1119. The story of his parents, if true, has an air of romance. The father, while on a pilgrimage to Jerusalem, was taken prisoner by the Saracens, and sold as a slave. The daughter of the master whom he served, conceived an affection for him; when he escaped from bondage she accompanied him to London, was converted to Christianity, and became his wife. Thomas a Becket was the offspring of this marriage. With powerful talents and great industry, he completed the requisite studies for the clerical profession, to which he was destined, at Oxford, Paris, and Bologna; and, on his return to England, his superior acquirements and prepossessing appearance attracted and secured the notice and friendship of the archbishop of Canterbury, from whom he obtained lucrative and distinguished preferment. The successful termination of a mission to Rome on the affairs of the church, proved his abilities in the management of public affairs; and a recommendation from the archbishop to Henry II. procured for him the favour of that monarch, by whom he was elevated to the high dignity of lord chancellor, loaded with civil and ecclesiastical offices, and entrusted with the education of the heir-apparent of the crown. His immense revenues enabled him to live in the most princely stile, to keep a numerous band of retainers, and to display a more magnificent expenditure than any subject in the kingdom. Ambitious of fame in military affairs and martial exercises, with a train of knights he accompanied the king in an expedition to France, and gave proofs of his skill and bravery in active warfare; and hunting and horsemanship were his favourite amusements. But with this accumulation of riches, honours, and distinction, his attachment to his sovereign, devotion to his interests, and gratitude for such unexampled favours, continued unabated.

The growing power of the church and its rapid encroachments on civil authority had greatly harassed the reign of Henry. In the vacant see of Canterbury he contemplated an opportunity of imposing a restraint on the increasing evil, by filling it with a submissive dependent of his own, and Becket probably at the same time saw a new scene of ambition opened before him. But on his elevation to the primacy, in 1162, he was no longer the servile flatterer and pliant courtier. Withdrawing from the world, he relinquished the chancellorship, subjected himself to the severest mortifications, and by his boundless charities commanded the highest respect and admiration; but he was no less jealous of the prerogatives

Becket.

of the church than his predecessors, and would suffer no interference of the civil power in the punishment of the clergy, even when they were guilty of the greatest enormities. Becket, with the other dignitaries of the church, had assented to the *Constitutions of Clarendon*, regulations drawn up for defining the powers of the clergy, and had solemnly sworn to maintain and observe them; but the pope's refusal to ratify this deed was accompanied with a dispensation to relieve him from the obligations of his oath. His renunciation was followed by an open rupture with his sovereign. He was compelled to leave the kingdom, and after a residence of six years on the continent, he was restored, through the mediation of the pope and the king of France, to his dignity and power. Reinstated in the archiepiscopal chair, he was not more accommodating than before his exile; and the king, indignant at his proceedings, is reported to have said, that "he was an unhappy prince, who maintained a great number of lazy insignificant persons about him, none of whom had gratitude or spirit enough to revenge him on a single insolent prelate, who gave him so much disturbance." Four barons impressed with these words, and determined to force the archbishop into submission, hastened to Canterbury, and found him at vespers in the church. Refusing to listen to their remonstrances, and defying their vengeance, he was slain as he knelt at the altar. His death happened on the 29th of December 1170, and in the 52d year of his age.

Few events have made a deeper impression on the public than the murder of Becket. Henry seemed to express the utmost regret at the barbarous deed, and dispatched a solemn embassy to Rome to wipe off the imputation from himself, and to conciliate the papal court. The church of Canterbury was regarded as polluted with the crime, and divine service had ceased to be performed in it for nearly a whole year, till it was reconsecrated by the command of the pope. Two years afterwards Becket was canonised; and in the succeeding year, when Henry returned to England, he submitted to penance, as a testimony of his sorrow and regret for the murder of the prelate. When he approached the church, he alighted from his horse, and in the habit of a pilgrim walked barefooted to the tomb of Becket. Having prostrated himself, and continued for a considerable time in prayer, he submitted to be scourged by the monks; and kneeling upon the bare stone he spent the whole day and night without refreshment. After the lapse of 50 years from the time of the murder, the body was taken up in the presence of Henry III. and a great concourse of the nobility, and deposited in a magnificent shrine erected by Langton, archbishop of Canterbury. The reputation of the miracles performed at his tomb, attracted pilgrims from all quarters, by whom it was enriched with the most precious gifts and costly offerings. Even foreign potentates were found among the devotees. Louis VII. of France performed a pilgrimage to this far-famed tomb, and bestowed on the shrine the most valuable jewel in christendom. The body was annually raised by the monks, and the day on which this ceremony was observed, designated *the day of his translation*, was kept as a general holiday. Every 50th year a grand jubilee, which lasted fifteen days, was celebrated to his honour; to all who visited his tomb at that time plenary indulgences were granted; and it is said that 100,000 pilgrims have been entered on the register at a time in Canterbury. A curious record is preserved, which shews the estimation in which St Thomas a Becket was held, by the disproportionate amount of the offerings made at the altars of Canterbury. In one year, at the altar of God, the sum offered was L.3, 2s. 6d. at that of the Virgin L.63, 5s. 6d. and at St Thomas's L.832, 12s. 3d.; and in the following year no offering whatever was made at the altar of God, the sum presented at that of the Virgin amounted to L.4, 1s. 8d. but at St Thomas's it was L.964, 6s. 3d. Henry VIII. pillaged this celebrated shrine of its rich treasures, cited the Saint to appear in court, and to be tried and condemned as a traitor, commanded his name to be expunged from the kalendar, and ordered his bones to be burned, and the ashes to be dispersed in the air.

Beckmann.

BECKMANN, JOHN, the ingenious author of a curious treatise on the origin and progress of economical and mechanical arts, was a native of the electorate of Hanover, and was born in 1739. By his father's death, when young Beckmann was only seven years old, the care of his education devolved on his mother; and having completed the elementary branches of literature, he was sent to Gottingen to finish his studies for the clerical profession, to which he was destined. But he was more devoted by inclination to physical science than to theological learning; and in 1762, on the recommendation of the celebrated geographer Busching, who then presided in the Lutheran academy at St Petersburgh, he was appointed professor of natural philosophy in that seminary. The harmony of the institution was soon after disturbed by dissensions, which induced Beckmann to relinquish his situation. Returning to his own country through Sweden, he made himself acquainted with the mode of working its valuable mines, and on his visit to Upsal he experienced much of the hospitality and friendship of the illustrious Linnæus.

The appointment to the professorship in the university of Gottingen, which he retained through life, took place in 1766. Beckmann seems to have possessed a peculiar facility of talent in the developement and application of science to the arts of life. It was the professed object of the institution which he now superintended, to arrange and illustrate the various departments of political and domestic economy. The novelty and interest of his lectures attracted crowded audiences; his instructions were not merely general descriptive details; but in the visits of his pupils, whom he accompanied to the work-shops of the artisan and manufacturer, he explained and elucidated the minutest processes.

In compliance with a laudable practice, which had been long established in the University of Gottingen, that every public teacher must be acquainted with what has been done throughout Europe in his own department, Beckmann entered on the arduous task of collecting information on the multifarious subjects of his lectures;—a task, the extent of which is only limited by the bounds of human knowledge, and from which an ordinary mind would have shrunk in despair;—a task which his singular talents for research, his peculiar powers of elucidation, and unwearied industry, have enabled him to accomplish in the most successful manner, and the fruits of which have appeared in *The History of Inventions and Discoveries*, one of the most curious productions ever presented to the world. In this elaborate collection, the origin of the arts of life is marked as distinctly as can be ascertained by historical evidence, and their progress is traced through ancient and modern times to their present most improved state. No reader can be disappointed in the perusal of this work, of which an English translation has been published. Beside various Memoirs in the Commentaries of the Royal Society of Gottingen, Beckmann was engaged in the latter years of his life in the *History of the Earliest Voyages in Modern Times*; and that part contributed by him bears the marks of his usual industry and research. He died in 1811; and, to the praise of his distinguished literary attainments, must be added the excellence of his moral character, in which great candour and modesty, warmth of friendship, and the utmost condescension and affability to his pupils, were the prominent qualities.

BEDDOES, Thomas, a learned English physician and medical writer, was a native of Shropshire, and was born in 1760. His early education was conducted at private seminaries, and at the Free Grammar School of Bridgenorth, where he was greatly distinguished by a retentive memory, close application to study, and rapid progress in classical literature. An accident which befel his grandfather, and which terminated in his death, led young Beddoes, who was then only nine years old, to watch the progress of the affection, and to consider the means of cure employed, and is said to have fixed his choice of his future profession, while the interest and acuteness which he displayed as a feeling and sagacious observer, attracted the notice and procured for him the lasting friendship of the attendant medical practitioner. In his sixteenth year he was admitted a student at Oxford, and in his literary exercises he soon acquired the reputation of an elegant classical scholar. About this time he began the French language; and when he entered on this study with no other help than a grammar and a dictionary, his reply to a friend who expressed his surprise at the boldness of the attempt, that in two months he would acquire a competent knowledge of it, and in which he actually succeeded, shews with what eagerness, facility, and perseverance he acquired languages; for with the same independent exertion he became master of Italian, German, and Spanish. But while he proceeded with ardour in the prosecution of general literature, he was not inattentive to the progress of physical science, and particularly to the brilliant discoveries in chemistry, which had just begun to dawn on the world. Natural history, especially botany and mineralogy, occupied his leisure hours during his college vacations.

Thus qualified, he repaired to London in his 21st year, to pursue the requisite studies for the medical profession; and while he was engaged in acquiring the knowledge of anatomy and physiology, he translated Spallanzani's *Dissertations on Natural History*, from the original Italian. In 1784 he fixed his residence in Edinburgh, and continued for three successive sessions to attend all the lectures in that celebrated seminary connected with his future destination in life; and within this period he translated and published Bergman's *Essays on Elective Attractions*, and superintended an edition of Scheele's *Chemical Essays*. Having been previously admitted bachelor and master of arts, he obtained, in 1786, the degree of doctor of medicine at Oxford; and having spent the succeeding summer in France, where he was fortunate in enjoying the acquaintance and conversation of the illustrious chemical philosophers, Lavoisier and Morveau, he was appointed, soon after his return, to the lectureship on chemistry in the university of Oxford. His lectures were instructive and popular, and drew together crowded audiences. Connected with his immediate pursuits, he published an Account of the Experiments of Mayow at Oxford in the 17th century, and to his curious researches has traced those discoveries which are the foundation of the science of modern chemistry.

But the residence of Dr Beddoes in this venerable seat of learning was of short duration. The dazzling scenes which the French revolution seemed at its commencement to hold out for the improvement and happiness of the world, could not pass unnoticed by an ardent and speculative mind. Beddoes was transported with the alluring prospect, and indulging in the political reveries of the day, took no pains to conceal opinions which ill accorded with the established modes of thinking of those with whom he associated. To this jarring of sentiment probably is to be ascribed his seemingly imprudent resignation of his lectureship. But the activity of his mind did not leave him unemployed; for about this time he published a treatise on mathematical evidence, and another on the cure of *Calculus*, *Consumption*, &c. with *Conjectures on other Objects of Physiology and Pathology*; and about the same time appeared his *History of Isaac Jenkins*, one of his most popular productions, in which he exhibits, under a fictitious narrative, the reformation of a habitual drunkard, and his return to sobriety and industry. The sale of 40,000 copies of this work in a short time, is a sufficient proof of the interest which it excited.

The establishment of a pneumatic institution for the purpose of patients inhaling certain kinds of air, with the view of curing diseases according to speculative principles suggested by modern chemistry, was long a favourite object with Dr Beddoes; and having surmounted many difficulties, he succeeded in his plan, and the institution was opened near Bristol in 1798. Its professed objects were not attained; but in the history of chemical science it will ever hold a distinguished place; for here, as the superintendant of the experiments, Sir Humphrey Davy commenced his brilliant career in the discovery "of the wonderful effects of *Nitrous Oxide*, or Gas of Paradise, on the system when respired." From the remarkable properties of this peculiar elastic fluid, the highest expectations were indulged of the benefits to be derived from this mode of conducting the cure of diseases; but it soon appeared that these hopes were visionary, and in the course of a few years the scheme was abandoned.

Beside the works already mentioned, Dr Beddoes was the author of a numerous list of treatises on medical subjects, and to most of them he has attempted to give a popular character to render them interesting and useful to the general reader, as well as to contribute to the improvement of medical education and rational practice. He was also the author of various political productions, a list of which will be found in Memoirs of his Life by Dr Stock. Dr Beddoes died in December 1808.

BEDE, or BEDA, usually designated the venerable Bede, one of the oldest English historians, was born at Wearmouth, in the county of Durham, in the year 672, was educated in the monastery of St Peter, and at the proper age was admitted to the priesthood. The greater part of his life was spent in a monastery near the mouth of the river Tyne, where he devoted himself to the exercises of religion and the pursuits of literature. In this retirement he composed his ecclesiastical history, a work which acquired him great reputation while he lived, and is still regarded of estimable authority. He composed a great number of other treatises on various subjects; he translated some parts of the Bible into the Saxon language; and his homilies were appointed to be read in the churches. He died in 735, and was buried in the church of his own convent, but his ashes were afterwards removed to Durham, and deposited in the same coffin with the mortal remains of St Cuthbert. The first collection of his works appeared at Paris in 1544, in three volumes folio, and the latest edition was published at Cambridge in 1722.

BEDFORD, an inland county of England, which has Buckinghamshire for its boundary on the south-west and west, Northamptonshire on the north-west and north, Huntingdonshire on the north and north-east, and Cambridgeshire and Hertfordshire on the east and south. The greatest length is estimated at 36 miles, and the breadth at 22 miles; the area in square miles exceeds 300, and includes about 300,000 square acres.

Bedfordshire presents a diversified surface of gently rising hills and low vallies. None of the higher grounds rises to any great elevation. The Chiltern hills, which skirt the southern extremity of the county, and traverse part of it, form the highest range, and are composed of chalk strata. The lower ridges consist of alluvial clay and sand, and branch off in various directions. In the uppermost stratum of chalk numerous layers of flints are regularly distributed. To this stratum, proceeding downwards, another body of chalk, harder and of a more solid consistence, and destitute of nodules of flint, succeeds. The thickness of the united chalk beds is not less than 400 feet, and below them are strata of chalk, marl, and a durable sand-stone. The alluvial clay is also of great thickness; and the beds of ferruginous sand, in some places of considerable extent, are from 150 to 180 feet thick. At the bottom of this stratum of sand are disposed the beds of fuller's earth, seven or eight feet in thickness, which have been long wrought in this and the neighbouring counties, for manufacturing purposes. In some parts of a clay stratum near the town of Bedford, thin beds of argillaceous schistus are met with, which are so strongly impregnated with bitumen as to burn like coal; and in the vicinity of the county town, beds of grey compact limestone appear, on which it is supposed the whole strata of the county repose. The inclination of the strata of Bedfordshire is to the south-east. A very large proportion of the soil of this county is alluvial, and composed chiefly of yellowish dark coloured clays. Peat soil is predominant in the bottoms of some of the vallies, and in this peat earth the proportion of sulphuric or vitriolic acid is considerable.

The Ouse, the Ivel, and the Ouzel, are the chief rivers. The Ouse, which is navigable from Bedford, and is subject to inundations, abounds with fish, and is remarkable for the size and superior quality of its eels. The Ivel is partly navigable, produces abundance of fish, and is famous for its gudgeon. The grand junction canal stretches for about three miles along the borders of the county.

The population of Bedfordshire, which was estimated in 1801 at 63,393, had increased in 1811 to 70,213. The annual value of the land at rack-rent is stated at L.280,000 Sterling. Bedford, the capital of the county, Ampthill, Biggleswade, Dunstable, are the principal market towns. The manufactures are chiefly thread-lace making, which, it is said, has declined, and given place to straw-plaiting. A whiting manufactory is established at Dunstable.

The Duke of Bedford, the Marquis of Bute, Earls Spencer and Upper Ossory, and Lord St John, possess large estates in the county. Wheat and barley are the principal corn crops, of which a good deal is exported. The management of the dairy is an object of attention, and affords a considerable supply to the London market. Woad is raised in some places for the use of dyers; and in the sheltered vales the culture of culinary vegetables for the neighbouring towns is extensive. The splendid experiments in various departments of rural economy, and particularly in the improvement of live-stock, which have been long carried on under the auspices of the Dukes of Bedford at Woburn abbey, if they are not on too grand and too expensive a scale for general imitation, could not fail to rouse attention and to stimulate exertion in similar undertakings.

BEDFORD, the capital of the county of the same name in England, stands on the banks of the river Ouse, which is navigable for small vessels to the German ocean, is 50 miles north from London, and includes a population which, according to the estimate in 1811, was equal to 4605. Bedford is described as a neat, clean town; the public buildings, some of which have been lately erected, are commodious and elegant; and the great inn raised on the spot formerly occupied by the castle is a magnificent structure. The manufacture of thread-lace is confined to females; wool-combing is a small branch of industry; some coarse woollen stuffs are made; lime is burnt in the neighbourhood; coak is prepared for drying malt; and roof-tiles for the supply of the contiguous villages.

Bedford has numerous charitable establishments, some of which are of great antiquity. The endow-

Bedouins.

ment of Sir William Harper, a native of Bedford, and afterwards, in 1561, lord mayor of London, is not the least remarkable for the increase of the fund and the mode of its application. He purchased 13¼ acres of land for L.180, in the parish of St Andrew, Holborn, and bequeathed it to the corporation of Bedford for the support of the grammar-school, and for furnishing dowries on their marriage to young women belonging to the town. The original rent was L.40. In 1668, it rose to L.99, on a lease for 41 years; and afterwards, on a building lease for 51 years, at the annual rent of L.150. Bedford Row and the adjoining streets were raised on this property; and when the leases were renewed, the net rent was L.4000 per annum, and expected on second renewals to rise still higher. But the application of one part of this fund has not been attended with beneficial effects. The prospect of L.20 as a dowry, has been the source of rash and unfortunate marriages, and has increased the demands on the poors rates, or added to the inhabitants of the work-house.

Bedford in the early periods of English history was the scene of many severe struggles between contending factions. The strength of the castle pointed it out as a place of great importance.

BEDOUINS, tribes of wandering Arabs, who inhabit the desert regions of Arabia, and other parts of Asia and Africa. The name is derived from an Arabic word, which signifies *desert*, and *inhabitant of the desert*. The Bedouins are regarded as the purest race of the Arabians, because they have no intercourse with other nations. They have lived from the remotest ages in tents, have never associated in towns or villages, and migrate from place to place in the desert, as safety, pasturage, and water for their flocks, camels, or horses, may require. The Bedouins live under the authority of a chief or *scheik*; the different tribes are independent, and sometimes in a state of warfare with each other; but the whole, descended from the same original stock, having the same manners, and professing the same religion, are considered as the same nation; and besides, one of the scheiks is acknowledged as the supreme ruler, with the title of *emir*, or prince.

The manners and customs of the Bedouins, whether they are found in Arabia or Africa, are nearly the same, and exhibit altogether the native simplicity of the pastoral age of society. From their wandering mode of life, they are subject to numerous privations, and have thus become robbers by profession. Many of the tribes who are in the vicinity of the route of travellers and caravans that traverse the desert, live by plunder. But with all this rapacity, the virtue of hospitality to strangers is highly respected, and rigidly practised. It would be regarded as the most unpardonable offence among the Bedouins, to violate in the slightest degree the rights of hospitality, even when an opportunity is offered of avenging an injury on an enemy. See Volney's *Travels in Syria*, &c. Sonini's *Travels in Egypt*.

BEE, *Apis* of Linnæus, a numerous genus of insects. See ENTOMOLOGY.

BEE.

Introduction.

THE object of the present treatise is to give such a description of the *habits* and *manners* of the *common honey-bee*, as will afford to the readers the latest and most accurate information respecting these interesting and useful insects; to investigate the nature and explain the uses of the products which they furnish, and to notice the most approved and advantageous methods of managing them. These subjects have always been deemed important, and have attracted the attention of naturalists and writers on rural economy, from the days of Columella and Virgil to those of Huber and Huish. It is only within these few years, however, and chiefly in consequence of the researches and experiments of the latter writers, that any considerable accuracy in the natural history of bees has been attained, and there are still a few disputed points which the most able investigators of modern times have hitherto failed in their attempts to determine.

Many causes have contributed to retard the progress of scientific knowledge and practical improvement in this interesting department of rural economy. The investigations necessary to clear up disputed points are extremely difficult; and experiments require to be frequently and carefully repeated, that hasty and erroneous conclusions may not be formed. It is remarkable, that the ablest investigators into the economy of bees, especially Huber and Huish, are completely at variance in many of the most important points; which is right, we presume not to judge, but shall, in the course of our remarks, state the opinions of both, leaving it to time and future experience to decide between them. The practical improvement of managing bees has been much impeded by prejudice and superstition. The favourite doctrine, that "old ways are always best," prevents many persons from adopting what both reason and experience have proved to be easy and judicious; and the popular superstitious notion, that "bought bees never thrive," and that they must be either *begged* or *stolen*, has, in this country, rendered the culture much less general than it would otherwise have been.

In the first part of this treatise, we shall exhibit a succinct view of the *economy of bees*; and in the second shall describe the most approved methods of *managing* them.

Economy.

PART I. ECONOMY OF BEES.

Description and varieties.—The general appearance of the honey-bee is familiar to every one, but there are some parts of its structure which require to be described in order to understand the particular functions which these parts perform.

In every hive, or separate colony, there are three kinds of bees, differing from each other in size, proportions, and peculiar organs. By far the greatest number, comprehending from 20,000 to 40,000, or more, are of a comparatively small size, being about six lines long, are furnished with a sting, and with imperfect ovaries or internal female generative organs. These are the working bees; they collect honey and wax, construct the combs, feed the young, and protect the hive from the incursions of other insects. From their internal structure, it is ascertained that they are essentially female, though but few instances occur of their laying eggs. The next in point of number, to the amount of 1500 or 2000, are larger and thicker than the former, being about seven lines long, have a duller flight, are devoid of sting, and are evidently of the male sex. These are called *drones*,—they take no part in the labours of the hive, and seem to serve no other purpose than impregnating the female. Over this numerous assemblage of workers and drones presides a single female bee, of more majestic port than the rest, longer than the drones by about a line, and, though of a more slender form, very strong and active. She is justly styled the *queen*, and is the only individual that uniformly lays eggs and produces young, so that she may be called the mother of the colony. Like the workers she is provided with a sting.

The structure of the working bees particularly demands our attention, as it illustrates the operations which they perform. They are furnished with a mouth and jaws, capable of biting and tearing substances of considerable solidity, and with a *proboscis*, or trunk, fitted for taking up liquid matters, and conveying them by the mouth into a capacious double stomach. It is still disputed whether the proboscis be tubular or solid, but the latter opinion seems at present to prevail, and it is supposed to be employed rather as a tongue than a sucker. The hairs that cover the bodies of these insects are so formed as readily to collect powdery substances; and their feet are constructed like brushes, so that these matters are easily swept off the body, and lodged in cups bordered with hair, that are hollowed in the third pair of legs. The sting, whose wound proves so painful even to man, and is speedily fatal to insects, is a very complicated weapon. It consists chiefly of two opposite rows of barbs, terminating in a point at the outer extremity, and so united as to form a tapering tubular canal that communicates with a bag placed within the belly, and filled with a very acrid poisonous fluid. This sting is rather an offensive than a defensive weapon, and is used almost solely for the purpose of destroying those enemies that presume to enter the hive, or of exterminating the drones when their services are no longer needed.

Queen.—The queen is in many respects the most important personage in the hive, as on her depends the continuance of the colony, and she conducts those numerous hordes that annually quit the parent dwelling in search of new habitations. She is therefore regarded with peculiar care and affection, and is never suffered to quit the hive except to head a corps of emigrants, or to fit herself for becoming the mother of a future race. But before we detail the interesting particulars that respect the functions and manners of the queen, we must attend the labouring bees, and describe the operations which they perform.

Operations.—As soon as a colony of bees is established in a hive, they commence their labours; and from the rapidity with which these proceed from the first, it is supposed that the swarm carry with them a quantity of materials to lay the foundation of their future works. As it is of the utmost consequence that they should be defended against the injuries of the weather, and as few hives are sufficiently close in their junctures for this purpose, the first object of the bees is to procure a natural cement, capable of filling up the chinks and crannies of their dwelling, and of resisting moisture.

Propolis.—With this view they collect from certain vegetables large quantities of a resinous matter, which, though soft and ductile when first obtained, has the property of becoming hard on exposure to the air. This has been called *propolis*. It is collected chiefly from the buds of certain trees, especially those of the pine tribe and the poplar, is of a reddish brown colour, of an agreeable aromatic odour, and so glutinous, that it is with some difficulty that the bees detach it from their legs. Besides lining the junctures of the hive, this substance is employed by the bees to envelope the bodies of snails and the larger insects which they have killed, but cannot remove from the hive, as this coat of resin has the effect of preventing the putrefaction of these dead animals.

Construction of combs.—Leaving a sufficient number of their comrades to protect the queen and hive, and carry on the internal operations of the colony, the workers set out in search of provisions and materials for building. They visit flower after flower, and cull from each those substances that are to supply both their present and future wants.

Their first object after obtaining a sufficient defence against the injuries of the weather, is to construct combs in which to lay up their provisions, deposit the eggs of the queen, and rear the young brood. Without at present enquiring into the nature and origin of the wax of which the combs are formed, we shall describe their general appearance, the particular form of the cells of which they are composed, and the method employed by the bees in their construction.

The combs are suspended in a perpendicular direction from the top of the hive, and are arranged parallel to each other, with an interval of only a few lines between them. Each comb is composed of two sets of cells, opening at opposite surfaces of the comb. The general figure of the perfect cells is that of a hexagonal prism, opening at the surface by its base, and separated from the opposite cells by a pyramidal cavity called its bottom. The opposite cells are so arranged, that the planes which form the terminating pyramid of one cell, concur to form the bottoms of three others of the opposite cells, so that they are not placed point to point. The cells which form the highest series of the comb have a different form from those that make up the body of the comb, for as two of the sides of the hexagon are cut off by the plane to which the comb is attached, the openings of these upper cells are irregularly five-sided. The edges of the comb are composed of small irregular cells, but to these there are generally attached distinct oblong structures, composed of large cells, for the reception of those eggs that are destined to produce queens, and are therefore called royal cells.

In forming the cells, the working bees detach with their hinder feet the plates of wax, which are prepared in a manner to be presently explained, from the rings of their belly, and carry them to their mouth, where the wax is worked till it become soft and ductile. Thus prepared, it is applied to the part from which the comb is to be suspended, or that to which an addition is to be made, where it is formed into a block of a lenticular shape, thickest at the top. The interior of each cell is formed by the bees scooping out the wax from this solid block, till its sides are sufficiently thin, an operation which requires the successive labours of many bees to accomplish. The pyramidal part of each cell is first formed, and then the sides are constructed of the wax that had been scooped out, or by the addition of fresh plates.

Several attempts have been made to explain the peculiarities of figure just described in the cells of the honey-comb, but none of them is altogether satisfactory. Buffon attributed the hexagonal form to the necessary and equal pressure of a number of bees occupied at the same time in contiguous cells, which he supposes at first to have been cylindrical, and to have assumed the shape of hexagonal prisms in consequence of this equal pressure. This hypothesis appears ingenious, but by no means accounts for the inequality in the size of the cells, for the pyramidal form of their central extremities, and for the nicety with which these extremities are adjusted on opposite sides of the comb. It is found, that though the natural direction in which the bees work is downwards, they can be made to build from below upwards, and in either way it appears that from the first completion of each cell it is of a prismatic form.

The cells of a comb when first constructed are soft and white, and their edges thin and sharp. By degrees they become harder, assume a yellow tinge and a glossy surface, and their outer edges become thicker and stronger. This is found to be owing to a coating of resinous varnish, similar to the propolis already mentioned.

Collection of honey.—The combs being thus prepared, the working bees proceed to deposit in them the provisions collected for the use of the colony, and the queen, when impregnated, begins to lay her eggs. The provisions of bees consist partly of honey and partly of pollen or farina. The honey they collect from the nectaries of flowers, licking it up with their proboscis, and conveying it by the mouth into the stomach. In its general properties, honey, when first collected, resembles a solution of sugar in water, with the addition of a little mucilage, but modified in taste, smell, and colour, by the nature of the plant from which it is collected. It evidently undergoes some change in the stomach of the bee, though in what this change consists is not distinctly ascertained. When the bees return to the hive, they deposit in cells the honey they have collected, by an action resembling vomiting, or deliver it over to the internal workers, who deposit it in the cells intended for its reception, and when these are full they are sealed up with a plate of wax.

It appears that the bees are not very nice in the quality of the saccharine juice which they collect. Their chief object seems to be abundance; and they are known to lay up a store of honey which, though probably affording an innocent nutriment to them, proves deleterious when taken into the human stomach.

Origin of wax.—It was long disputed what was the nature and origin of the wax that forms such an abundant product of a bee-hive. Most naturalists supposed it to be derived from the pollen, which was conceived by some to be taken into the stomach of the bee, and there fitted by digestion for the formation of wax. M. Duchet, previous to 1778, hazarded the opinion, that it was formed from honey; and Wildman actually saw plates of wax at the bottom of a hive, appearing as if moulded by the bodies of the bees. These scales were observed by John Hunter in actual contact with the bodies of these insects; but it was reserved for Huber to put this matter beyond a doubt, by his observations and experiments.

He has, we think, nearly proved that wax is a secretion formed within peculiar cavities, of a pentagonal shape, that are situated on each side of the middle process of the abdominal scales in the belly of the working bees, and that it may be seen exuding in a fluid state on puncturing these cavities. It is secreted chiefly by a distinct set of bees, who are provided with a more capacious stomach than the other workers, and consume a greater quantity of honey. It is this honey that constitutes the source from which the wax is produced; and it appears that the saccharine principle of the honey is the essential part, as even a greater quantity of honey is formed by those bees who are fed on sugar and water, than by such as live on honey. These facts were experimentally ascertained by Huber, and have been verified by frequent observation. We are aware that Mr Huish ridicules this opinion of Huber and his followers, and asserts, that, according to the old notion, honey is formed from pollen taken into their second stomach, and there elaborated with water or honey; but it is long since we have been convinced that ridicule is not the test of truth; and we think that, in more instances than one, Mr Huish has substituted this seducing talent in the place of sound argument or logical induction.

Pollen.—A third substance collected by bees is *pollen*, or the *farina*, contained in the anthers of flowers. This is a powdery resinous matter, composed of minute globular particles, capable of coalescing into a coherent mass. The bees collect it by means of the brushes attached to their feet, and the hairs that cover their body, combining a number of particles into a pellet, which they deposit in the basket-shaped cavity in the middle of the hinder legs. This pollen is laid up in appropriate cells, and being destined for feeding the young brood, has very properly been termed *bee-bread*. A surprising quantity is collected for this purpose, a pound having been known to be carried into a hive in one day. It is curious that the cells are never filled with pollen, but this matter is covered up with honey.

The labours of bees in collecting these materials depends much on the state of the weather. When the sky is calm and serene they work with activity and dispatch, but in wet weather they confine their labours chiefly to the internal operations of the hive. It has been remarked that they are peculiarly diligent in a thunderous state of the atmosphere, probably foreseeing that such a state will terminate in rain.

Impregnation, &c. of the queen.—When a sufficient number of cells have been constructed, and provision made for the future brood, the queen begins to prepare herself for the exercise of the important function of increasing the population of the hive. With this view, as we are informed by Huber, she seizes the opportunity of a fine day to sally from the hive, and seek, during her aerial excursion, the embraces of the male, and among the numerous drones that fly about at these times she soon gains her object, and returns in a state of impregnation. This opinion of Huber, which is said to have been verified by other naturalists, is combated with much pleasantry by Mr Huish, though we think he has not successfully disproved it, and has certainly given no more satisfactory hypothesis of his own. He roundly asserts, that the queen remains a virgin though she lays prolific eggs, an anomaly in nature which we deem at least equal to some of those opinions which he treats with so much ridicule. He contends, indeed, that the eggs are fecundated by the drones after being deposited in cells by the queen; but how this is effected he does not inform us. Within a few days after having become a perfect insect, the queen is capable of becoming a mother; and it is even necessary, for the proper exercise of this function, that her impregnation should take place within twenty days after she has left the royal cell.

Within about forty hours after impregnation the queen begins to lay her eggs in those combs that are in the middle of the hive, and continues this process for many months, laying sometimes 200 eggs daily. She first lays those of workers and afterwards those of males. She appears conscious what kind of eggs she is about to lay, and carefully examines the diameter of the cells in which she is to deposit them, taking care that she does not introduce them into cavities too small for their perfect developement.

The eggs destined to produce future royal issue are among the last deposited by the queen in royal cells, provided for that purpose. A curious and hitherto unaccountable circumstance has been ascertained respecting this function of the queen. If her impregnation has by any means been retarded for above twenty days, she lays eggs from which only drones are produced. It is found that the laying of her eggs is obstructed by cold, and she generally gives over laying in the autumn, but begins again in the spring.

Developement.—The eggs laid by the queen bee are of an oblong oval form, and a bluish white colour. In the course of three days from their deposition, the larva or worm is hatched. It is curious that the eggs of all the three varieties are hatched in the same period, but the progress of the larva is different in each. The worm of the working bees continues in that state for five days, then occupies about thirty-six hours in spinning its cocoon, in which in three days it becomes a nymph, and in twenty days from the deposition of the egg comes forth a perfect bee. Drones attain the perfect state in twenty-four days, but the queen-bee escapes perfect from the cocoon in sixteen days. During this time the larvæ are carefully supplied with food formed of pollen, made into a jelly, probably by being mixed with honey, for about six days, when they cease to eat, and are shut up within their cells, though still carefully watched by the working bees. When the perfect insect is set free, the cell in which it had been confined is cleaned out and converted to other uses.

Manners of the queens.—Particular care is bestowed by the workers on the larvæ of future queens. They are fed with a richer and more stimulating jelly, and supplied with it in greater quantity than the ordinary worms. Thus the developement of the royal larvæ is accelerated. It commonly happens that two or more queens are hatched about the same time, in which case they become rivals, and the weaker fall victims to the one which is most powerful. Huber has minutely described the combats of these rival queens, which exhibit an extraordinary combination of ferocity and caution. They rush together with great fury, and take such a position with their bellies opposite each other that they might easily be mutually wounded by their stings; but as in this case both would fall, it seems provided by nature that when they feel themselves in this position they should separate. The surrounding workers, however, stimulate the rivals to a new combat, and the stronger seizing a favourable opportunity, suddenly darts her sting into the belly of her adversary, and inflicts a mortal wound,—thus displaying in this Lilliputian monarchy the same jealousy that is observed in some despotic eastern empires, admitting no sister near the throne.

The old queen entertains a similar jealousy towards the future royal race, though her own offspring. About the time when the young queens have nearly acquired their perfect state she frequently visits the royal cells, and would inevitably destroy the young queens there secluded, were she not prevented by the workers. In the early part of the season, before a colony has left the hive, the bees, aware of the necessity of preserving a sovereign for the future exigencies of the state, are particularly careful to guard the approaching young queens from the attacks of their elder rival, and accordingly surround the entrance to the royal cells with a strong intrenchment of wax, and keep constant watch to prevent the hostile attacks of the reigning queen. But when the season of swarming is past, and any farther production of queens may tend only to disturb the peace of the hive, they seem rather to encourage and assist the reigning queen in the work of exterminating her rivals.

The presence of a queen is essentially necessary to the welfare and tranquillity of the hive. Wherever she goes she is accompanied by a numerous retinue of her subjects, who throng around her and attend her with anxious solicitude. Taking advantage of this attachment of the bees for their queen, several persons have displayed feats in the management of these insects which have been beheld with astonishment. The celebrated Wildman once presented himself before the Royal Society with several swarms of bees upon his person. One hung pendulous from his chin like a large and bushy beard, another enveloped each arm, and a fourth surrounded his body. He had acquired so much dexterity in handling the queens, that it was easy for him to seize and confine them wherever he pleased, and the bees attached to each queen following their leader formed these remarkable groups.

If the presence of the queen be productive of these exhilarating effects on the community, it is not surprising that her loss should produce effects of a very opposite nature. When by any accident the bees find themselves without a sovereign, a loss which it appears they do not immediately perceive, the hive for a time becomes a scene of disorder and despair. Abandoning the care of the young brood, the bees run about in the greatest agitation, examining every part of the combs, and rushing impetuously out of the hive in search of their lost queen. This state of agitation continues only for a few hours; for when they find the queen irrecoverable, they, by a wonderful instinct, contrive a method of repairing the loss by transplanting select larvæ of working bees to newly constructed royal cells, where they feed them with the same kind of stimulating jelly with which the legitimate royal brood is usually nourished, till by this care and diligence they, in fact, convert into real queens those worms which, under ordinary circumstances, would have produced only workers.

Hence is derived an important conclusion in the natural history of the bee, that both queens and workers originate from eggs of the same kind, and become either the one or the other, according to the care bestowed on them, and the food by which they are nourished.

Swarming.—Pretty early in the season, generally in May or June, when the old queen has deposited a sufficient number of eggs to supply the parent hive with future inhabitants, she prepares, with a numerous train of followers, to quit the settlement in search of a new habitation. This emigration constitutes what is called *swarming*, and the colony is termed a *swarm*. Satisfactory reasons have not been assigned for this occurrence; for though it generally takes place when the hive is crowded with inhabitants, or is likely to be overstocked by the future progeny, it not unfrequently happens when there is abundant room. Swarming seems to depend chiefly on the queen; and it is found that just before leading out the swarm she is in a state of great agitation. The usual signs of a swarm being about to leave the hive are the following: For several days many of the bees cluster round the mouth of the hive, and, especially in the evening, hang in groups from the front of the board on which it is placed; an unusual and agreeable humming noise is perceived in the evening before the swarm issues forth; and, on the day of swarming, fewer bees are seen to issue from the hive, or enter with their usual load. To these signs may be added the appearance of a great number of drones, and an uncommon stillness suddenly succeeding very great agitation within the hive. When every thing is prepared the bees crowd to the entrance, and the queen first escaping, is speedily followed by her attendants, consisting of both drones and workers in the usual proportion. The swarm first takes but a short flight, and then rests on some bush or tree in the neighbourhood of the parent settlement, the queen alighting first and the other bees clustering round her. If not now arrested they soon prepare for a longer and more distant excursion, till they find a situation suited to their purpose of establishing a new colony, which in their natural state is generally the hollow of a tree, or within the roof of some secluded building.

It appears from the observations of Mr Knight, that scouts are sometimes detached from a hive several days before swarming, in order to seek for a situation adapted to the reception of the new colony, though in these cases no works are constructed by these purveyors. Generally more than one swarm issues from the same hive during the season, and if the summer has been very favourable three swarms have been known to proceed from one hive. In this last case, however, the parent settlement is so much weakened that its inhabitants seldom survive the winter. The first swarm is always led forth by the old queen, and the succeeding swarms by the eldest of the young queens in succession.

Extermination of drones.—A few drones accompany each swarm, probably for the purpose of impregnating the queens; but when all the swarms have left the hive, and the remaining workers in the old settlement have nearly finished the labours of the summer, and are looking forward to their winter retirement, they prepare to rid themselves of this unnecessary, and now unwelcome part of their population. About the commencement of autumn, sometimes as early as the end of July or beginning of August, they begin their work of extermination. Great bustle and much agitation prevail throughout the hive. The unfortunate males, driven from the combs on which they generally hang in careless indolence, are pursued with implacable resentment to the bottom of the hive, where they fall in one general massacre, transfixed by the stings of their former associates, and their dead bodies are thrown out upon the ground. So complete is this extermination, that if there remain any larvæ or nymphs of drones within the cells, they are dragged from their asylum and involved in the common destruction. Only in one instance are the drones suffered to remain in a hive through the winter, namely, when the settlement has lost its queen, and there appears no probability of a new one being produced before the ensuing spring.

Mr Huish contends, that the drones are not killed by the sting of the workers, as is generally supposed, but rather by their mouths biting them near the root of their wings. His great objection to the commonly received notion is, that when a bee stings a person it leaves its sting behind it and dies. Now, it by no means follows that this is the case in other instances; and indeed, were it so, of what use is the sting to these insects if the employment of it were universally to prove fatal? He also objects, that the venom of a bee is not likely to prove mortal to another bee; Why not? Does not the venom of a rattlesnake, or a Cobra de capello, prove mortal to the animal itself, when made to wound itself?

Preparations for winter.—When the scarcity of flowers warns the bees that they must expect no further supply of honey, they adopt the greatest economy to spare their winter store. Besides the honey which they still occasionally procure for persent subsistence, they collect the sweet excrementitious juice deposited by the insects called *Aphides*, on the leaves of certain plants, or exuding from their upper surface, and known by the name of *honey-dew*. They also frequently commit depredations on neighbouring hives, and on these occasions such formidable conflicts sometimes take place as materially to weaken both the invaders, and those who stand on the defensive. As winter approaches the bees consume but little of their provisions, but pass much of the cold weather in a torpid state, roused however occasionally by the penetrating influence of a mid-day sun. During the coldest weather they appear to sink entirely into torpidity.

Ventilation.—Several particulars in the economy of bees, are more properly connected with the physiology of insects. But here it ought to be remarked, that, like all other animals, bees require continual supplies of fresh atmospheric air to preserve their healthy existence. As the hive is generally very close, admitting air only by a single opening, the bees fall on a contrivance to promote the circulation of air through their habitation. To effect this purpose several of them place themselves near the entrance, and, by a constant and rapid motion of their wings, agitate the air, and this agitation is propagated by other individuals, placed at proper distances within the hive. Thus, a free ventilation is produced, and the temperature of the hive is preserved equal and moderate. During their winter torpidity, the necessity for such a constant supply of air is diminished, and they appear not to suffer by the stagnant atmosphere of the hive.

Enemies and diseases.—Bees are exposed to the attacks and depredations of numerous enemies; but we shall notice only those which are found in this country. Among quadrupeds the badger sometimes overturns the hives, and robs them of their contents, unawed by their stings, which are not able to pierce his thick and shaggy hide; and field mice occasionally force an entrance, especially while the bees are in a torpid state. Among birds, the bee-eater, the shrike, the swallow, the sparrow, the tit-mouse, the cuckoo, and most poultry, greedily devour them, and the wood-pecker is said sometimes to succeed in breaking through the hive, and thus attacking its inhabitants. Of reptiles, lizards and toads watch for and seize them when they alight near their retreats; but their most formidable enemies are among the insect tribes, especially the wasp, the hornet, the ant, the larger species of spiders, and the moths. This last is the most insidious, but not the least destructive of their enemies, as it insinuates itself into the hive, and deposits its eggs among the combs, where the larvæ when developed make terrible havoc, and frequently compel the bees to quit their hive. A very large species, the *sphinx atropos*, or death's-head moth, is, in some countries, particularly destructive, and is supposed to prevent the bees from exerting themselves in their own defence, by a peculiar shrill sound which it emits, and which is said to resemble that sometimes uttered by the queen bee. We believe this moth is not common in Britain; but on the continent it sometimes deprives the farmers of their whole stock of bees. To protect themselves against these intruders, the bees contrive, towards winter, to straiten the entrance into the hive, by raising a narrow passage of wax and propolis capable of admitting only one or two of their number at a time.
